PLICATION OF THE ROUND AND ANTERIOR FOLD OF THE BROAD LIGAMENT ON THE ANTERIOR SURFACE OF THE UTERUS FOR RETRODISPLACEMENT *

R. C. COFFEY, M.D.
PORTLAND, ORE.

ANATOMIC AND SURGICAL PRINCIPLES

This presentation is made more to illustrate the anatomic and surgical principles underlying the entire subject of the treatment of retroversion, than to set forth any specific mechanical detail. The uterus is very largely an intra-abdominal organ. All intra-abdominal organs are supported almost entirely by peritoneal folds. The peritoneum is supported in turn by a loose connective tissue which holds it loosely but persistently to the abdominal wall except at its upper attachment, where it is firmly fixed and blended with the diaphragm. Strictly speaking, the abdominal organs, which we refer to as intraperitoneal, are all extraperitoneal, inasmuch as every organ lies between two layers of peritoneum made as if the organ had been pushed into the peritoneal sac from the outside, and had become adherent to it.

New ligaments are formed during fetal development and rotation, by the contact of two peritoneal surfaces which adhere, blend, and become obliterated at point of contact. This may be illustrated by the rotation of the colon, which goes upward and to the right and adheres to the peritoneum of the posterior abdominal wall and thereby forms the mesocolon. The spleen rotates to the left, comes in contact with the peritoneum of the posterior abdominal wall, adheres to it, obliterates the endothelial coverings and thereby the ligament of the spleen is formed and it is fixed on the left side. The omentum grows from the lower border of the stomach down over the transverse colon and adheres to it at the point of contact, its surfaces blend and we have the gastrocolic ligament or gastrocolic omentum. If the peritoneal surface of the stomach is plicated by bringing the anterior superior border and the anterior inferior border together and holding them firmly by peritoneal sutures, all of the space enclosed by this line of sutures becomes obliterated. If the omentum is sutured to the abdominal wall and held firmly, the surfaces blend and a complete partition is made across the abdomen. If the lesser omentum is plicated for a gastroptosis, Beyea has found that the surfaces blend and the omentum or ligament is permanently shortened.

The Kelley operation proves more conclusively than anything else the certainty of the blending of peritoneal surfaces, for we find that after Dr. Kelley's operation (which does not use one-twentieth the amount of peritoneum found supporting other organs of equal weight), in only a small percentage of cases does the uterus fall backward, and in nearly all of those cases in which the uterus does fall backward, the ligament is found, not broken, but attenuated to a thread. This operation has probably been done more times than any other intraperitoneal operation, with the exception of the removal of the appendix, tubes or ovaries; and with remarkable success when we consider that it first struck the vital point of treating displaced organs. Alexander unwittingly used the same principle in drawing out the round ligament and with its covering of peritoneum which blended at the internal ring, shortening the anterior fold of the broad ligament just so much as there was of peritoneum passing through the internal ring. The operation was later spoiled by meddlers who pushed the peritoneum back off the ligament, as a result of which the operation has fallen largely into disuse. The Gilliam, the Mann, the Simpson, the Baldy-Webster and all operations which are used to-day and have been found to be successful, use the peritoneum of the broad ligament; consequently I think the formulation of the following rule is justified: "Two peritoneal surfaces brought together and held firmly in an aseptic state, adhere, blend, and obliterate and the contiguous surfaces lose their endothelial covering, becoming continuous at the point of peritoneal contact."

The uterus, however, differs from the other peritoneal organs in that it is permitted a wider range of motion because of its functions; also, in that it is connected directly with the outside and therefore must be protected from extrusion. Because of the necessity for extraordinary mobility, the peritoneum of the broad ligament, the principal ligament, is attached extensively before and behind to the sides of the uterus and well down near its middle between fundus and cervix. Thus a very extensive attachment of peritoneum supports the uterus and, because of the large amount of loose connective tissue holding the peritoneum to the fixed wall of the pelvis, gives it a wide range of mobility. According to Nature's law of conservation, the uterus, which is so loosely attached, is turned in the pelvis, so that it lies practically crosswise.

Owing to the fact that such a variety of positions must be assumed, it becomes necessary to have some other means of automatically or involuntarily poising this organ and keeping it in this position at right angles to the body. Therefore the round ligament becomes a necessity, and is, histologically, perfectly constructed for such a function, as indicated by the following definition, taken from Sobotta:

---

* Read in a symposium in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixty-First Annual Session, held at St. Louis, June, 1910. Some articles of this symposium appear on later pages of this issue and others, with the discussion, will be printed next week.

In addition to the broad ligament, the uterus possesses other ligaments which are to be regarded as a continuation of its musculature. The most important of these is the round ligament, which is essentially a cylindrical or slightly flattened muscular cord, 12 to 15 cm. in length, which takes origin on either side from the anterior surface of the uterus in the vicinity of the uterine extremity of the tubes, and runs at first almost horizontally, then forward and downward between the layers of the broad ligament covered mainly by the anterior one. In the vicinity of the uterus the ligament is thickened and consists solely of connective tissue and nonstriated muscle but in its course through the inguinal canal it usually receives fasciculi of striated fibers from the internal oblique and transversalis which are continued on it for a varying distance, frequently extending almost to the uterus but never passing externally beyond the inguinal ring. He further says: "Similar continuations of the uterine musculature are the recto-uterine which run in peritoneal folds of the same name and connect the superficial musculature of the rectum with that of the uterus. The uterosacral ligaments are connective-tissue fasciculi which accompany the muscular similarly named folds to the region of the second and third sacral vertebræ where they fuse with the peritoneum.

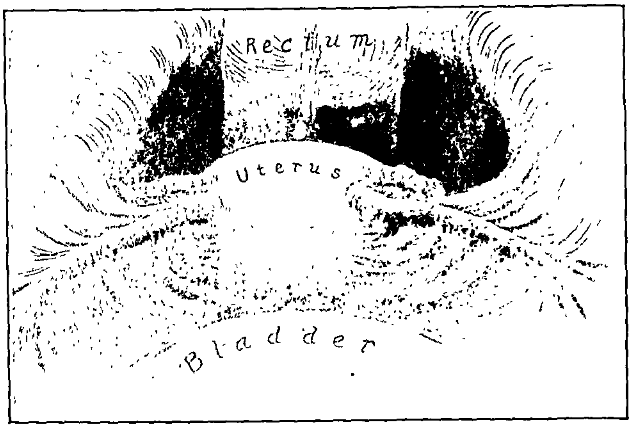

Fig. 1.—Relations in partial retrodisplacement of the uterus.

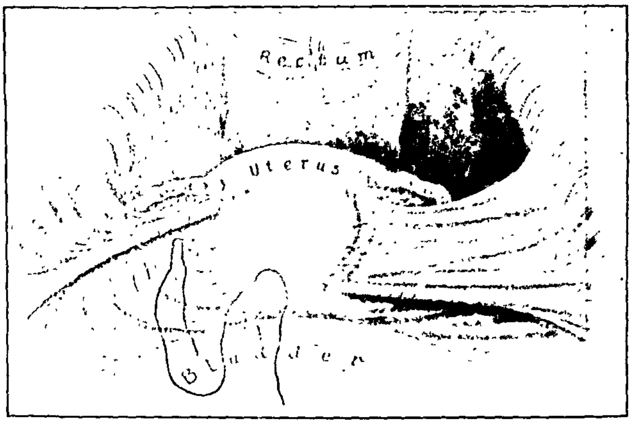

Fig. 2.—First step in author's round and broad ligament plication.

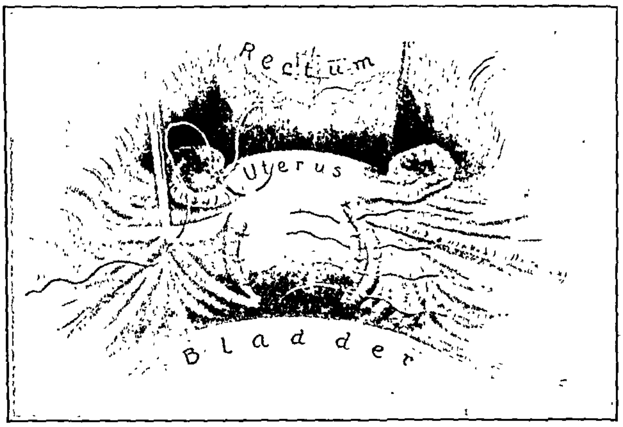

Fig. 3.—Second step in author's operation.

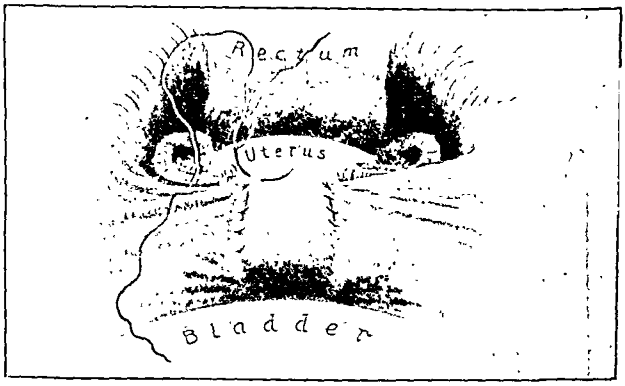

Fig. 4.—Third step in author's operation.

Taking up the physiology, we find that a muscle fiber has no other function than that of contraction and producing motion. We also know that a muscle fiber will under no circumstances stand a continuous strain, and that a muscle is therefore totally unfitted for taking up the work of a ligament proper; consequently, the only physiologic function for which the round ligament could be used would be for producing motion, aside from the function performed by the connective tissue, which is an extraordinary precaution to prevent the uterus from being extruded. It is therefore very evident that the function of the round ligament must be that of automatically poising the uterus during the various positions assumed by the individual and thus preventing it from becoming a dead weight on the broad ligament.

OPERATION

Following the early operations of double salpingectomy and oophorectomy, in which the broad ligament was tied off *en masse*, and in which the round ligament was frequently included, a large percentage of the patients developed a retroversion. If one or both round ligaments are destroyed by traumatism, retroversion will usually take place later on; therefore it seems that the round ligament and the broad ligament are equally essential to the proper holding of the uterus in position —the broad ligament to carry the constant weight, the round ligament to poise it on this support in a manner making it easy to carry. Such being the case, the ideal operation for retrodisplacement of the uterus should shorten the broad ligament and at the same time avoid permantly fixing and thereby hampering the movements of the round ligament. Therefore I submit the following operation:

Before beginning the operation proper, break up adhesions, treat adnexa, lifting the uterus, and pack a sponge back of it which leaves it in the position shown in Figure 1. Then seize the round ligament about an inch and a half from the uterus, and with a No. 2 or No. 3 chromicized catgut, stitch to the anterolateral border of the uterus at the beginning of the vesico-uterine fold. Place three or four similar sutures between this point and the uterine end of the ligament (Fig. 2). Thus a double fold of the broad ligament is brought over to the side of the uterus.

Seize the ligament an inch and a half further on and bring it up to a point just above and internal to the uterine end of the round ligament and fasten with a chromicized catgut suture. Place three or four more sutures between this and the first suture at the vesico-uterine fold (Fig. 3). Thus, two more peritoneal or broad ligament layers are brought over to the side and front of the uterus.

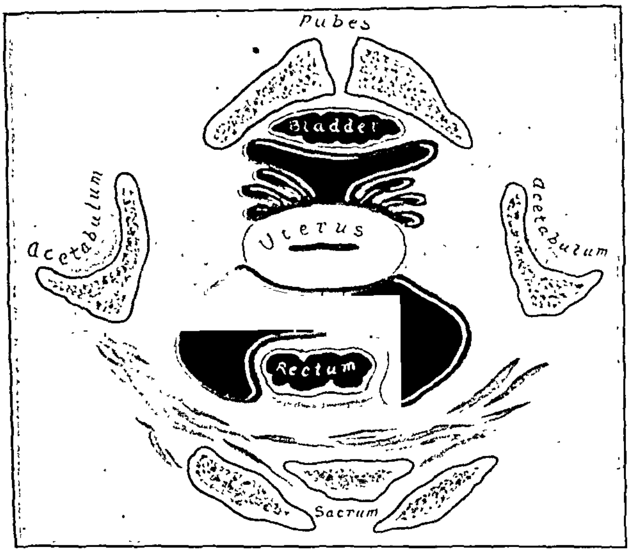

Fig. 5.—Sectional view, showing scheme of plication operation.

With a No. 1 or 2 chromicized catgut continuous suture, bring a fold of peritoneum from each side over the line of interrupted chromicized sutures. This continuous suture may include as much of the peritoneum as necessary to bring it taut; care must be made to avoid pulling in the bladder. (Fig. 4). Be careful not to include the entire thickness of the round ligament in any of the rows of sutures.

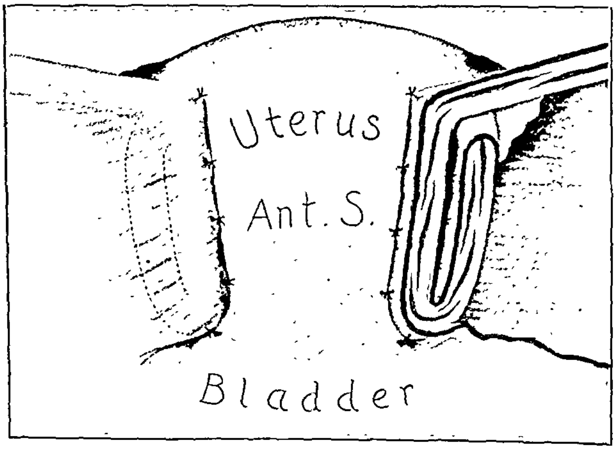

Fig. 7.—Scheme of second step of operation shown in perspective on the left and in sectional view of the right.

I have personally performed 272 operations for retrodisplacements of the uterus by using this method. In twelve other cases continuous sutures were used all through, in an attempt to shorten the operation. After the twelve operations by the continuous method, four patients relapsed very soon and the other eight have not been heard from. After the 272 operations by the method described, using the interrupted sutures, I have heard of only two cases of recurrence; one after an operation for prolapsus in an old woman, another in which the operation was followed by volvulus, requiring a secondary operation and drainage. In fact, I have not examined these patients and do not know that recurrence has taken place. I have learned directly of eighteen women who have borne children since. In these, no dystocia has been noticed. I have personally examined four of the eighteen after labor and found the uterus in good position. The other fourteen have been examined by the family physician and the uterus has been found in good position. Of the 272 patients five have required a later operation for other diseased conditions in the lower abdomen, which has given an opportunity to observe the condition following the operation. In all five cases, the broad ligament was found holding the uterus in perfect position. The ligament was normal except that the anterior fold seemed slightly thicker. The round ligaments, one of which in all cases, and both of which in some cases, had been attenuated to the size of a very small cord, had regained their normal size

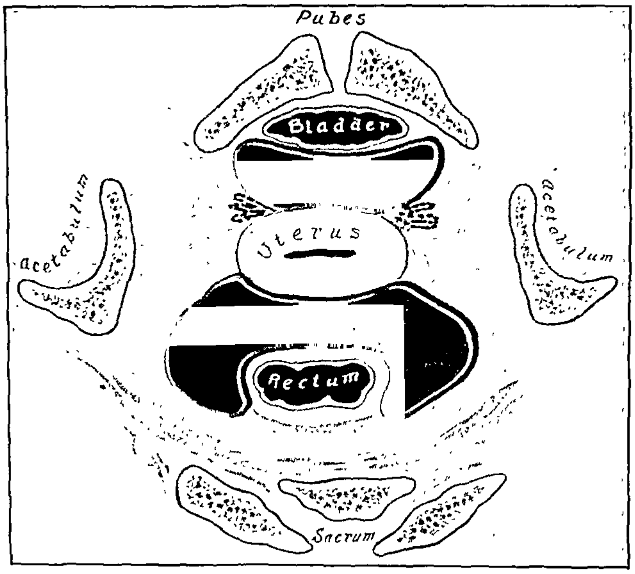

Fig. 6.—Sectional view, showing end-results of plication operation. Dotted lines represent obliterated peritoneal areas.

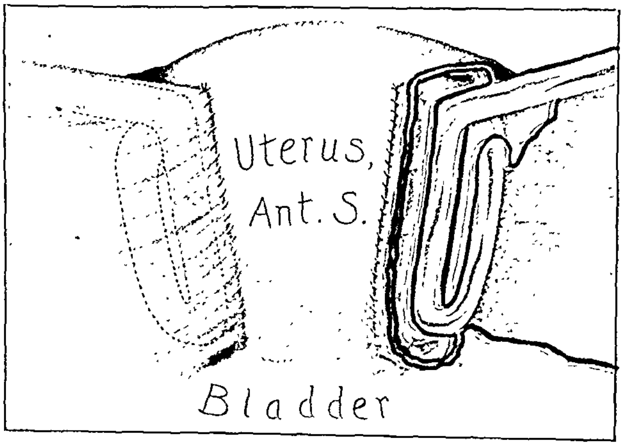

Fig. 8.—Scheme of third step shown in perspective on the left and sectional view on the right.

and their normal position under the peritoneum and, in fact, had reestablished relations that were normal in every respect. Therefore I feel justified in presenting Figures 7 to 11 to illustrate the manner in which the round ligament unquestionably restores itself to its normal condition. I may here state that this is easily proved by making a cloth uterus and broad ligaments in which a round ligament made of an elastic cord is placed. By folding the round ligament and the broad ligament on the surface of the cloth uterus, as I have done in the operation, taking care to glue the cloth broad ligament to the surface of the cloth uterus, thus corresponding to the blending of the peritoneum; by using sutures which can be either withdrawn or cut, in order to free the elastic cord, it will be found that the cord will slip out from between the layers of the cloth broad ligament, producing exactly the same condition I have found in my cases, minus the blending of the adjacent peritoneal surfaces which obliterates all peritoneal spaces.

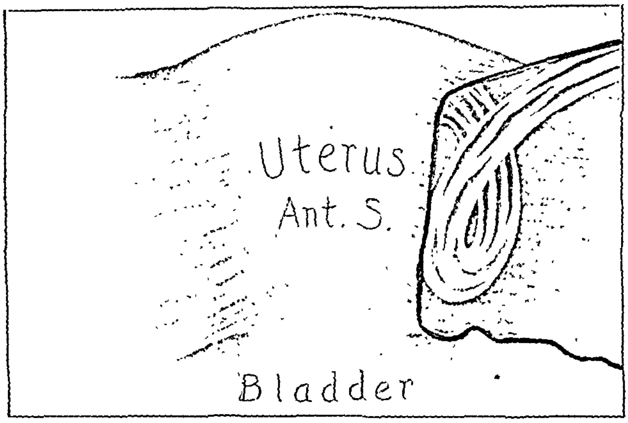

Fig. 9.—Round ligament freeing itself and straightening under the peritoneum.

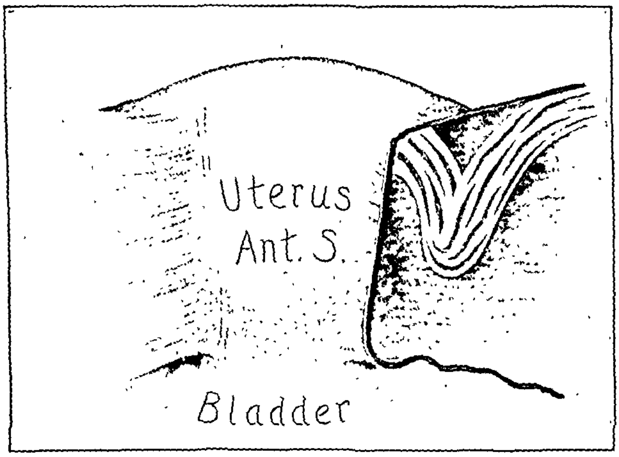

Fig. 10.—Final step; round ligament straightening itself under the peritoneum of the round ligament.

Figure 7 shows the second step of the operation in perspective on one side and a sectional view of the same step of the operation on the other side. In the sectional view, representing the round ligament as being very much attenuated, the muscle cells are few.

Figure 8 shows the completed operation in perspective on one side and a sectional view of the completed operation on the other side with the same attenuated ligaments.

Figure 9 shows a broad ligament some weeks after operation on one side, and on the other side, the theory of the gradual freeing of the round ligament under the broad ligament as represented. The round ligament has had time to rest, the catgut sutures have been partially absorbed, the muscle fibers, performing their normal function of contraction, are coming closer together, thereby straightening the ligament out under the peritoneum.

Figure 10 is an extension of the same process, in which the round ligament is becoming straighter and shorter and the muscle fibers are becoming correspondingly *more numerous*.

Figure 11 shows the round ligament straightened out under the broad ligament and the establishment of a normal cord:

In this operation, as proved by results seen afterward, all the requirements of the anatomic and surgical principles set forth have been fulfilled. The broad ligament, which is the principal support of the uterus, has been shortened, and the action of the round ligament has not been permanently hampered but on the contrary, it has been permitted to regain its normal strength so that while the uterus is supported constantly by the broad ligament, it may also be poised to suit the changing positions of the body by the restored round ligament.

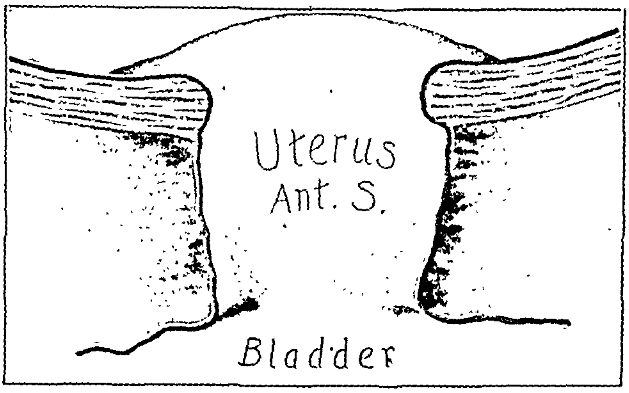

Fig. 11.—Round ligament restored to normal position under the peritoneum.

Dr. W. B. Holden, my office neighbor, has done this operation more than 50 times without recurrence as far as he knows, and states, in a personal communication that the results are so satisfying that he never thinks of doing any other operation for retroversion of the uterus.

Dr. Suttner of Walla Walla, Wash., has done the operation regularly for some time (more than 150 operations), and patients have been pleased with it. The observations of all these operators, taken with my own, seem to indicate that the comfort to the patient is greater in this operation than in any other operation having the same object. The absence of the backache, which is represented as following operations which permanently fix the round ligament, is a very noticeable feature. Previous to the development of this operation, I had done approximately 200 Kelley operations with very good success as far as holding is concerned. The anatomic condition left after the operation was unsatisfactory in a considerable number of cases. Labor was difficult in a proportion of the patients.

In some cases habitual abortion occurred and a very large percentage of the patients complained of the old backaches, pulling on the abdomen, and a train of nervous symptoms which were even worse than the original. I may here state that I followed Suttner's lead in performing the plication operation in cases in which the uterus was already pregnant. Suttner deliberately did this plication operation in two cases at the second month of pregnancy in order to prevent abortion, which had previously been habitual about the third month as a result of the displaced uterus. In each instance, the child went on to full term and was born without difficulty. In one of my cases the patient was pregnant at the time of operation but did not know it. She went on to full term and was delivered. In another case, the patient, an unmarried woman, was found to be pregnant two months. The plication operation was done regardless of the condition. The wedding ceremony was performed the night after the operation. Pregnancy went on to full term and the child is now several months old. I presume that these pregnancies would continue with any of the other round ligament operations in just the same way, but I mention these cases to show that while this operation seems to comprise a good deal of surgery the traumatism must necessarily be of a superficial nature.

Corbett Building.

THE RELATION OF THE TEETH TO THE DEVELOPMENT OF THE JAWS AND FACE *

FREDERICK B. NOYES, B.A., D.D.S.
CHICAGO

In considering the structure of all multicellular organisms, and, in fact, in the very simplest aggregations of cells into tissues, it becomes apparent that there are two essential parts: the cells, which are the vital units; and intercellular substances, which give the physical characteristics to the tissue. The latter are always material which have been produced by the vital activity of the protoplasm, but which are not living matter; that is, they have no vital properties but are dependent on the protoplasm for formation and for the maintenance of their chemical character. In tissues, the vital characteristics are given to the protoplasm by the cells, the physical characteristics by the intercellular substance. Protoplasm, which has long since been recognized as the physical basis of life, is always of a soft and more or less gelatinous character, and of it alone, nothing resembling a highly organized creature could be formed. Other substances therefore have been produced by the protoplasm for the purposes of protection, support, rigidity and strength. Always the protoplasm is the active agent by whose chemical activity the protecting or supporting substance is formed. There are two types of formation. The first consists of cells which develop substances inside of the protoplasm to give rigidity or strength This class is illustrated by certain cells found in the lobster and other similar creatures, but this type of supporting cell has apparently proved insufficient or not adapted to higher developed forms. In the other type the protoplasm develops, on its surface or about it, formed materials which give protection and support, either in the form of rigidity, or strength, or both. The simplest example of this class is found in the cell walls of plants. It is important to note that the necessity for physical properties which are impossible for protoplasm itself is the cause of the appearance of intercellular substances.

In the very beginning of evolution, therefore, physical conditions and necessities led to the formation of substances by the protoplasm which gave it support and protection. In the higher animals certain tissues have developed such materials for the support and assistance of the more vitally active tissue, and therefore have been called the supporting or connective tissues. In these tissues the cells form and maintain materials which give qualities of strength and rigidity to the tissue and enable it to serve as the framework of the organism. The intercellular substances have been called into existence to meet physical and mechanical conditions. The connective tissues are the most adaptable of all tissues and respond most quickly to conditions of environment. The mutation of these tissues or their power to change from one variety to another is their most striking characteristic. The cells control the intercellular substances to form more, to destroy what has been formed, or to change its character; and their activities are excited in response to physical or mechanical conditions.

In the process of growth and function they are continually changing. Embryonal connective tissue develops into fibrous tissue, fibrous tissue into cartilage, and cartilage into bone. In bone, which is the highest form of tissue for rigidity, mutation is the most striking characteristic. It may be formed from fibrous tissue directly or through the medium of cartilage, and it always retains a large amount of cellular elements which can at any time destroy and reform the intercellular substances. In fact, bone should always be considered as a fibrous tissue which has developed in itself intercellular substances of a different sort to meet special mechanical conditions. In other words, there is always in contact with the calcified intercellular substance of bone, on its surface and in spaces within it, undifferentiated connective tissue, the cells of which are capable of developing into any sort of connective tissue cells. It is the presence of these embryonal cells which makes bone a plastic tissue. There are three varieties of bone: subperiosteal, Haversian system, and cancelous. In other papers I have emphasized the characteristics of these classes, and I assume that all are familiar with the minute structure of each. At present I wish to emphasize the transformation from one variety to another that occur in growth and which are in fact going on continually throughout life under the influence of mechanical conditions.

In bone showing subperiosteal bone on the surface, a portion of compact or Haversian system bone, and cancelous bone beyond, if this bone is growing in one direction subperiosteal bone will be laid down in layers parallel with the surface. When a certain thickness has been formed large spaces or canals will be absorbed out of it, forming what are known as Haversian spaces and around these concentric layers will be laid down, converting them into Haversian systems. Only enough compact bone is formed to meet the mechanical stress of the position. As soon as an excess has been formed absorption begins in the Haversian canals, cutting out large spaces around which a few lamellæ are formed, producing cancelous bone. If the bone is growing in the opposite direction concentric layers will be laid down around the spaces of the cancelous bone, making it more compact and large absorptions will occur under the periosteum, cutting deep into the Haversian system bone, after which a few layers of subperiosteal bone will be

---

* Read in the Section on Stomatology of the American Medical Association, Sixty-First Annual Session, at St. Louis, June, 1910.

added to the surface. In such absorptions the entire surface is not attacked at one time, but in one area there will be a large absorption while in an adjoining there is a slight rebuilding.

Figure 1 illustrates the first type. It is a section of the buccal cortical plate of the mandible of a sheep. On the surface is shown a little subperiosteal bone in which only one or two Haversian systems have been formed. Next is seen the Haversian system bone which has been destroyed from within and rebuilt with bone of more open structure. The first type of growth occurs in the direction toward which force is being exerted; the second type occurs on the surface from which force is being exerted. It may be stated as a generalization that the bone is more dense, but less in amount on the side toward which force is exerted, and greater in amount, but less dense on the side from which force is exerted. These generalizations become important in orthodontia. These conditions are illustrated in Figures 2 and 3. Growth has been progressing toward the buccal side. In other words that is the direction toward which force has been exerted, and the compact bone is less in amount, more dense in structure, while on the lingual side it is greater in amount but less dense in structure.

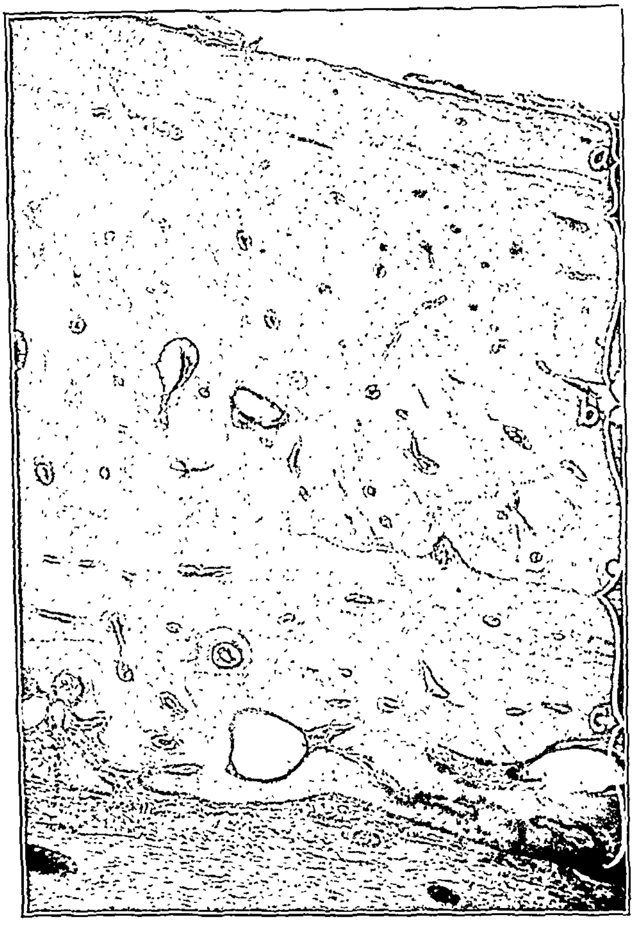

Fig. 1.—Buccal cortical plate of mandible of sheep; a, subperiosteal bone; b, Haversian system bone; c, rebuilt bone of more cancelous character.

Professor Cope, in a long article,[1] elaborates the idea that the bones have developed in response to mechanical conditions, that the form, size and structure are the expression of adaptation to mechanical environment. He treats the subject entirely from the evolutionary standpoint. If we consider the subject from the standpoint of the development of the individual we are led to similar conclusions, and become more and more impressed with the fact that bone is formed in response to mechanical stimuli. This is true of the bone as an organ, and equally true of the minute structure within it.

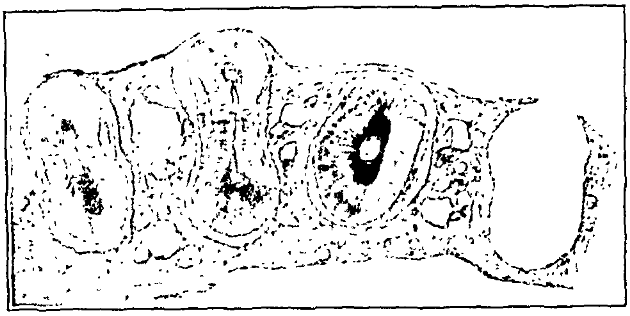

Fig. 2.—Transverse section through the alveolar process and the roots of the first and second bicuspids and first molar teeth; the buccal plate above the lingual plate below; the alveolus of the first bicuspid, to the right, empty.

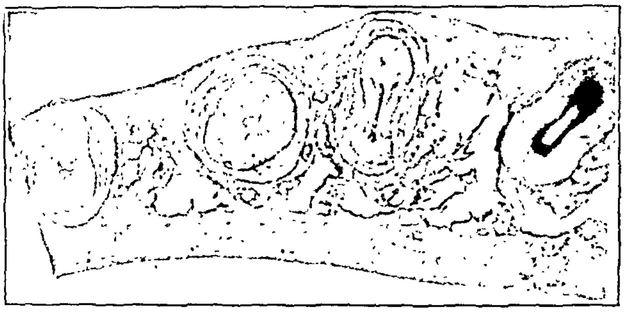

Fig. 3.—Transverse section deeper in the process; the buccal plate above, the lingual plate below, the first bicuspid to the left.

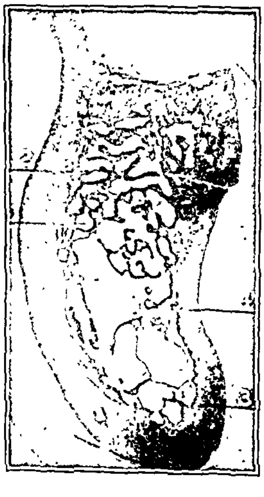

Fig. 4.—Section of human mandible between second and third molars.

Some years ago, Walkoff, in an elaborate study of the jaws by radiographs, showed that the direction and character of the spicules of cancelous bone within the substance of the bone are not the result of chance, but that their direction and arrangement were determined by the forces to which the compact bone of the cortical plates was subjected. If we examine sections of the mandible we shall find that not only is its general form determined by the mechanical conditions to which it has been subjected, but the cancelous bone is being continually reformed to adjust it to the stresses received on its surfaces.

Figure 4 is a decalcified section of a human mandible which was made to study the arrangement of the lamellæ as a record of the growth of bone. The subperiosteal layers are very few at almost all parts of the section. The cancelous bone in the alveolar region has been built and rebuilt to support the cribriform plates forming the walls of the alveoli for the roots of the molars during their movements in development, and the record of this rebuilding is left in the arrangement of the lamellæ.

---

[1] Cope, E. D.: The Mechanical Causes of the Development of the Hard Parts of the Mammalia, Jour. Morphol., 1888, iii.

Figure 5 shows a field from position 1, Figure 4. Notice how plates have been cut off and built on with layers in a new direction and how additions have been made at different times.

Figure 6 is taken from position 2, Figure 4. These spicules are a regular patchwork. At *a* is a bit of old spicule which ran in an entirely different direction, and there is another at *b*. These changes have not been the result of chance, but each new formation has been the response to some mechanical stimulus received through the substance of the bone.

Figure 7 is from 3, Figure 4, and shows the rebuilding that occurs during growth. There are large areas showing lamellæ which were at one time parallel with the surface in which comparatively few Haversian systems have been formed. This was probably during the most active period of growth, the later subperiosteal layers being much more completely replaced by Haversian systems.

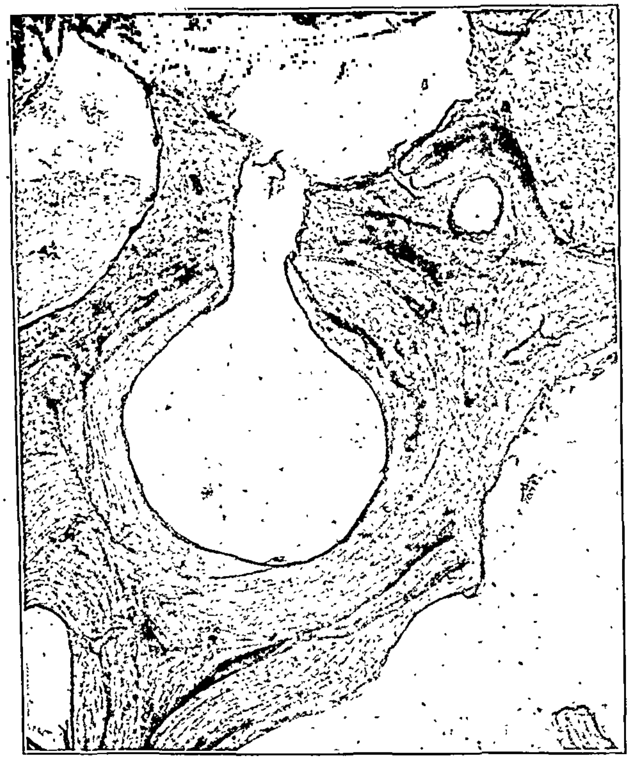

Fig. 5.—Cancelous bone from 1 in Figure 4, showing the rebuilding of the spicules and addition of layers at different times.

Figure 8, a field at 4 of Figure 4, shows wonderfully well the outline of the absorption spaces that have been rebuilt and at several places on the surface the marks of removal of bone by the periosteum, and in one or two places slight rebuildings.

In the growth of the jaws, therefore, bone is formed on the surface by the periosteum, the peridental membranes, and the articular cartilage, and is absorbed and rebuilt within, adapting it to all of its mechanical influences. We may say, therefore, that the adult bones are the result of all the mechanical conditions to which they have been subjected.

It would be impossible within the limits of this paper to consider in detail all of the forces which exert mechanical influences on the jaws. Probably the first and most important is the force exerted by the growth of organs enclosed in, or surrounded by the bones. This includes the growth of the tongue and the muscles surrounded by the jaws, and the muscles which lie against their surfaces, but more important, the growth of the teeth which are enclosed in the substance of the bone. Not much is known about the nature or the amount of the force generated by the growth or multiplication of cells. More has been done in regard to the growth of plant than animal cells but our knowledge is very meager. The force is probably very considerable, but acting through very small space. The growing roots of plants move stones, and some experiments have been made to determine the weight that could be lifted by the growth of a rootlet. The phenomena of osmotic pressure are involved in the problem and this involves the question of blood-pressure. There are some analogies

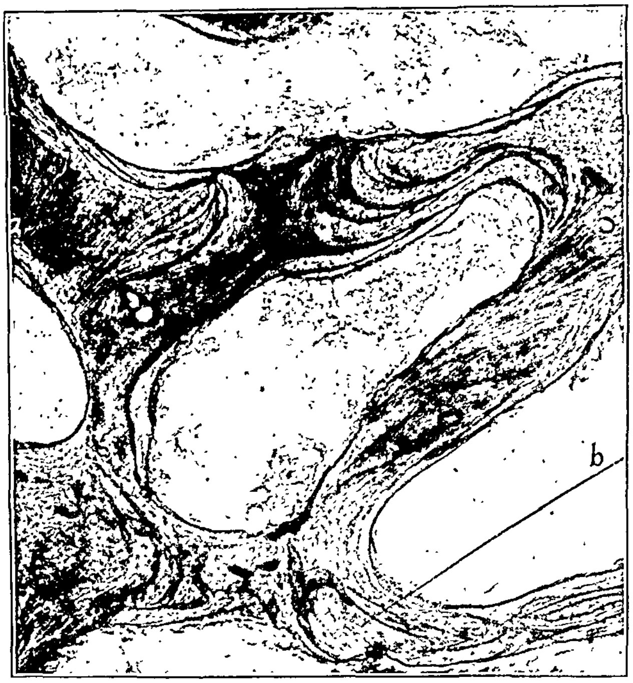

Fig. 6.—Cancelous bone from 2 of Figure 4; *a* and *b*, bits of old spicules.

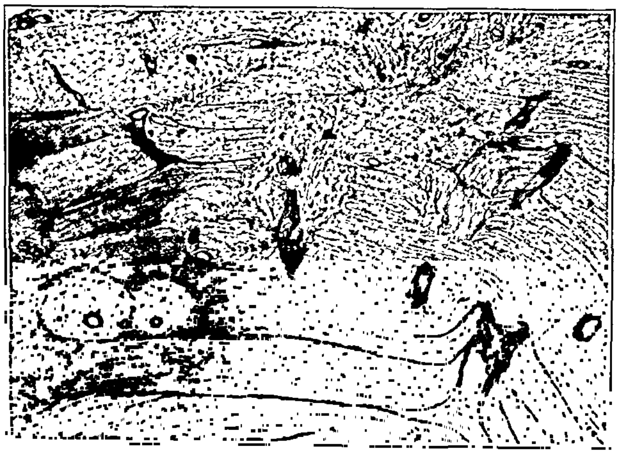

Fig. 7.—Compact bone from 3 of Figure 4, showing formation of Haversian systems in old subperiosteal bone.

between the force exerted by the growth of protoplasm and that generated by the expansion of wood fiber, by the absorption of water, but the whole subject is too deeply complicated for any such superficial analysis. Whatever may be the explanation, the growth and the multiplication of cells produces very considerable force; and the growth of the teeth within the substance of the jaw produces mechanical conditions which are very important in the development of the bones of the face.

In a paper recently read before the Illinois State Dental Society I presented a more elaborate analysis of this topic, only the more important phases of which can be given here. While the temporary teeth are erupting they are continually being carried occlusally by the growth of their roots, the alveolar process growing up around them. As the roots of the anterior teeth are completed, they are still pushed forward, upward and outward, by the development of those distal to them. As soon as the temporary dentition is complete, the temporary teeth—alveolar process and all—are forced to move, by the development of the permanent teeth, which lie in crypts below them. In the paper referred to, the relation of these crypts to the roots of the temporary teeth was examined in detail; here it is sufficient to say that the growth of the permanent incisors and cuspids first causes the development between the median line and the region of the mental foramen and later the development of the bicuspids and second and third molars cause the growth which increases the distance from the mental foramen to the ramus. The development of the long roots of these teeth will carry the temporary teeth, alveolar process and all, downward, forward and outward in the upper jaw, upward, forward and outward in the lower. If we examine sections of the alveolar process about the temporary teeth we shall see that this growth is accomplished by the formation of subperiosteal bone on the outer and inner surfaces, and subperidental bone at the margin of the process and around the alveolar.

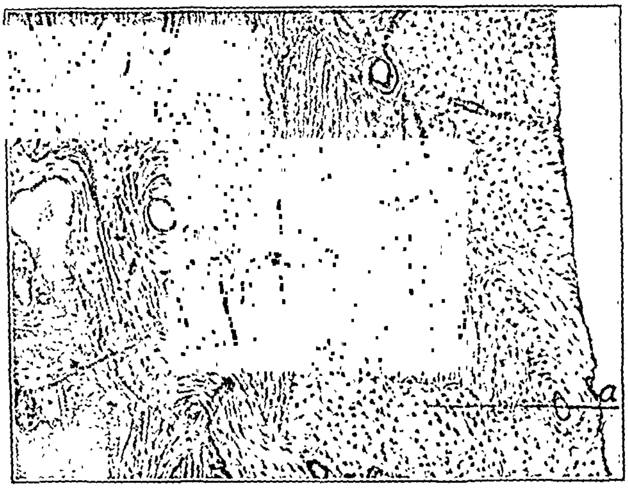

Fig. 8.—Compact bone from 4 of Figure 4; *a*, a rebuilt portion

In the production of the alveolar process the peridental membrane and the periosteum work together. As soon as a certain amount of solid layers have been formed, large absorptions occur, which are partly rebuilt by concentric or Haversian system lamellæ, which may be again partly rebuilt and destroyed. The important factor is that the teeth are moving in an occlusal direction and the bone is being built and rebuilt under the influence of the mechanical conditions, so that at the later stages of their use the bone of the temporary alveolar process shows an immense number of formations at different periods. The growth of the permanent tooth does not cause absorptions simply of the bone forming the immediate wall of its crypt but osteoclasts appear all through the bone enlarging the spaces and opening up the structure. Apparently the bone is weakened in this way until what is left can spring under the force and then a new formation is begun to strengthen the tissue.

I have been especially impressed with the way the force exerted by the growth of the teeth in the crypt is responded to all through the substance of the bone covering them or in fact throughout the jaw. The result of these tissue changes is that when the temporary teeth are finally pushed off there is only a remnant of the temporary alveolar process left, and to this additions are at once started to attach the erupting permanent tooth. The influence of the growth of unerupted teeth continues to cause growth of bone and movements of the previously erupted teeth until the third molars have taken their places. During all of this period the action of muscles has been reacting on the bone. First, the muscles of mastication attached to the ramus and the coronoid process rest against the digastrics, geniohyoids and geniohyoglossi attached to the anterior part, the teeth and especially the first molars acting as the fulcrum. It is apparent, therefore, that if the first molars are in abnormal relation the position of the fulcrum is shifted, and the balance of the forces is disturbed, and it is very apparent that if the lower first molars are mesial of their normal relation the result is an overdevelopment of the mandible; if they are distal there is an underdevelopment. This is the necessary result of the changed distribution of forces in response to which bone is formed.

The effect of the function of swallowing, I believe, has not been appreciated. Every normal person swallows about once every two minutes. In each set of muscular contractions which constitute the act there is a distinct and considerable thrust against the lingual surfaces of the bones and the teeth. Every thrust is a stimulus to the connective tissue cells. The mouth if normally closed is entirely occupied by the tongue, and the base of the tongue is held against the palate and the pillars of the fauces in such a way that a partial vacuum is produced, which assists in the support of the weight of the mandible. This constitutes a *mechanical impulse to* the growth of bone which is very important in lowering the roof of the mouth and consequently increasing the depth of the nasal cavity from above downward.

The normal action of the lips and cheeks is a most important factor, as we are reminded by the disturbance of growth caused by abnormal function of these muscles. Finally, to sum up the entire matter, I have endeavored to show that both phylogenetically and ontogenetically, bone is produced in response to mechanical stimuli; that in bone formation living cells produce formed material to give strength and that the vital activity of these cells is excited in response to mechanical influences. We have examined some of the many sources of force or energy which affect the vital activity of the cells, and as a result of these considerations we may say that the adult bones are the result of all the forces exerted on them and distributed through their substance by the occlusion of the teeth. If the occlusion is normal the forces are perfectly balanced, and a harmonious and symmetrical development is the result. In proportion as the occlusion deviates from the normal there is a disturbance of the harmony of development. The preservation of normal occlusion is necessary therefore not only for the proper mastication of food, but for the proper development of the face and proper function of respiration and swallowing.

ABSTRACT OF DISCUSSION

Dr. M. H. Fletcher, Cincinnati: I have done some of this class of work, and I have derived an enormous amount of pleasure and profit out of it. Those who have tried to do work of this character know that it entails an enormous amount of labor. A filling which may be too high, or the moving of teeth, or the treatment of the diseases of the sockets, and in fact almost everything we do in the matter of treatment of live tissue, brings these laws into play. I have been especially interested lately in the growth and repair of the cementum, and in several places Dr. Noyes has shown features that are especially instructive to me. I should like to see specimens more in detail as to the growth of cementum—where it begins and where it ends. The tissues lying about the roots of the teeth are subject to disease and repair to a marked degree, and we must understand these laws that we may intelligently treat diseases of the bones and teeth.

Dr. B. E. Lischer, St. Louis: I yield to none in my appreciation of the valuable contribution to dental science which Dr. Noyes has given us. I question one point, however, on which he laid much stress while explaining some of the slides on the screen. I refer to the theory of the elongation of roots and their probable rôle as a mechanical factor in the dentitional process. It was advocated many years ago by Wedl and since found wanting. Other theories proposed as a plausible explanation of the mechanism of eruption are the pressure theory (pressure of succedaneous teeth), the alveolar theory of Albrecht, the granular theory of Baume, the pulp theory of Wallisch, the functional theory of Robin and the blood-pressure theory of Constant, also as modified by Tomes. The latter is the only accepted one. The objections to the theory of the elongation of roots are as follows: (a) many impacted teeth with fully developed roots never erupt; (b) in the crocodile the developing teeth travel sideways for a considerable distance at right angles to the long axes of the roots; (c) most teeth in the course of eruption travel a greater distance that the entire length of their root or roots; (d) many teeth are erupted before their roots are fully formed.

Dr. Stewart L. McCurdy, Pittsburg: These hypertrophies of bone come from inflammatory conditions, from irritation, or from the projection of bone into the tissues or into the muscles following accident. The presence of syphilis stimulates not only hyperostosis but also endosteitis, and in addition the growth of the entire shaft of the bone, the entire bone becomes involved. Then in another instance diminished growth of the shaft occurs, as in achondroplasia, yet the epiphyses grow just as though the shaft were normal. In other words, the epiphyses are supplied by blood-vessels from entirely different sources than the shaft. Again, there may be hyperostosis of the epiphysis of a long bone, the shaft remaining perfectly normal. This entire subject of growth and development of bone is much clearer in my mind since I have heard Dr. Noyes' paper. The architecture and the reconstruction of the bone bring to my mind most strongly the law of conservation. As nearly as I can repeat that law, it is: Bone is deposited in the various parts of the body as it is needed; then Nature immediately begins to reconstruct that bone, and when it is not needed absorption takes place to diminish the bone to the normal size to perform its function. This is Wolf's law.

Dr. Eugene S. Talbot, Chicago: I think that Dr. Noyes has demonstrated that these forms of absorption are due to irritation. The point which Dr. Lischer makes is rather in Dr. Noyes' favor. All these conditions he mentions act as stimulants to bone development and assist in bone absorption and regeneration. In animals, the animal is either losing the function of bone, or he is developing rudimentary structures, so that cannot be considered here. Dr. Noyes has shown absorption due to irritation. There are, however, two points on which he did not touch, and which Dr. McCurdy mentioned in regard to the bone development and absorption, and that is the nervous system. In the case of *arrest of development* we have arrest in ontogeny, due either to some condition *in utero* or to disease, such as scarlet fever, pneumonia, or any other constitutional disease early in life. On the other hand, large jaws, those measuring 2½ inches in diameter, are due to want of resistance in phylogeny; in other words, arrest of development in phylogeny from the lower animals, such as the anthropoid apes, etc. In that case the large developed bones take the line at least resistance toward the lower vertebrates.

Dr. M. H. Fletcher, Cincinnati: I did not discuss the idea of pressure in the eruption of teeth or any other force, because I leave that just as I leave the differentiation of cell life in any other part of the body. If anyone can tell why a blade of grass grows, or why union of the male and female cell finally produces the epiblast, the mesoblast and the hypoblast, or why the presence of the dentin against the periosteum of the dental follicle induces a layer of cells which produces cementum then I think we are near to answering these questions. The practical feature I get from this is that under certain conditions Nature will reproduce certain tissue, and that in order to reproduce the new she must first carry away the old. Now it seems more important for us to know in what condition to put tissues in order to have repair, when there is broken-down tissue from disease, and the presentation of Dr. Noyes is a beautiful display of these laws.

Dr. Frederick Noyes, Chicago: I did not emphasize the elongations of the roots alone, and I did not emphasize the succedaneous teeth alone, or any one thing alone, but what I did try to state was that connective tissues are tissues of environment, and that they respond to mechanical stimuli, and that the elongation of the root necessarily produces a mechanical stimulus. It cannot help it. Consider for a moment the form of the root, the relation to the surrounding tissues and the fact that there is multiplication of cells in that space which produces force. So long as the root continues to grow it must exert a mechanical influence. The objections cited were that action and reaction are equally opposed in direction and if the resistance above the tooth is greater than the resistance at the apex, the apex will move and not the crown. I emphasized the fact that in the development of the tooth the floor of the crypt was pushed through the cancellous bone and did not react on the plate above until it reached the cortical plate at the lower border of the jaw, and the resistance was greater below than above and then the other end had to move.

Dr. McCurdy brought out several things which I could not go into, and, in particular, the idea that with mechanical stimulus without nourishment, growth is impossible. There may be mechanical stimulus, but if the blood-supply be cut off there can not be growth. I did not mention this because it is an inhibiting factor, not a developing factor. It is an important factor in the discussion, however.

Dr. Talbot referred to the influence of the nervous system, and that is a field which has important bearings in this connection. The point cited by Dr. McCurdy, that we would have changes throughout the substance of the bone beyond the region of the inflammation, indicates a nerve connection between the two, which, when a growth is set up in this position in response to mechanical stimulus, continues its action in a field beyond. In the same way, an irritation of one tooth may cause development of dentin within the pulp chambers of all the teeth within the same nerve-supply.

The most important thing which I wanted to bring out was that from a phylogenetic standpoint, from the beginning of evolution apparently connective tissues respond to mechanical conditions. Dr. Brooks stated as the greatest characteristic of life, the ability of adaptation to environment, and the characteristic of the connective tissue cell is to adapt itself to mechanical conditions. Following that idea through, we find that it is the mechanical influence to which the vital activity of the connective tissue cell responds with the changes in the structure of the tissue both in reconstruction and in production.

ELECTRIC ANALGESIA, AND ELECTRIC RESUSCITATION AFTER HEART FAILURE UNDER CHLOROFORM OR ELECTROCUTION*

LOUISE G. ROBINOVITCH, M.D.
NEW YORK

Electric analgesia was applied successfully for the first time, in animal, then in human surgery, by myself. Successful local application of this analgesia in human surgery is reported by Dr. M. M. Johnson.[1] I administered this analgesia. I have reported successful application of this analgesia in animal surgery and electric sleep in clinical work in all the issues of the *Journal of Mental Pathology,* commencing with 1906. The part of this paper treating of electric analgesia and sleep will be published elsewhere for reason of want of space here.

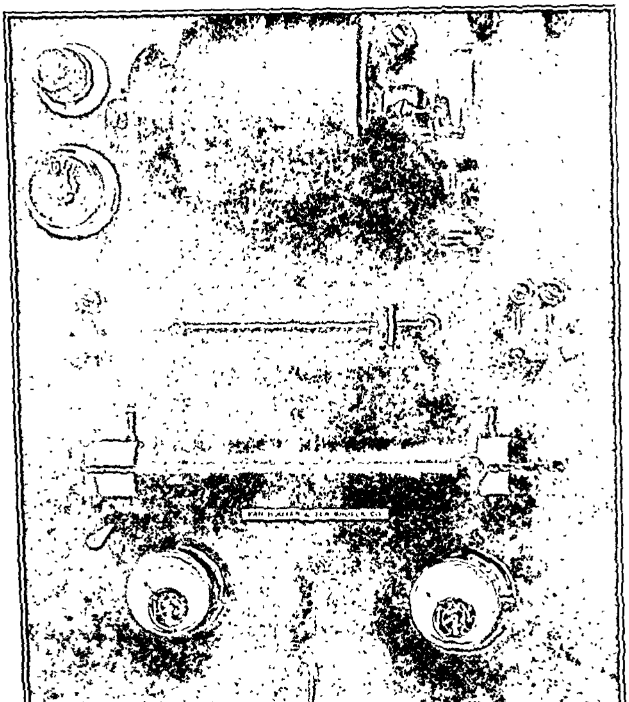

Fig. 1.—Author's model of wheel interrupter with fixed period of passage of current.

It is possible to resuscitate, by means of electric currents, subjects in a condition of apparent death caused by chloroform, ether, morphin, electrocution, etc. The first important researches into resuscitation of electrocuted subjects were made at about the same time by Professor Battelli[2] in Europe, and Dr. R. H. Cunningham, in this country.[3] Both authors used enormous currents for causing single electric shocks with which they attempted to restore life after ventricular tremulation had set in. Professor Battelli used 4,800 and 2,400 volts respectively, of alternating currents (amperage not stated). The means was not practical because one shock caused with such high voltage was all the heart could stand; a second shock killed the animal definitely, if it was not already dead.

Professors Leduc and Rouixeau[4] tried to resuscitate animals by means of direct interrupted currents of low *tension,* but they committed their predecessors' error of including the animal's head in the circuit. Besides, they used the lethal current for producing the shocks. The *method was useless in cases of dogs.*

While experimenting on the cerebral circulation during electric epilepsy[5] I saw, through a trephined opening in the skull, that every electric shock caused profound anemia of the brain at the time of the closure of the circuit. This led me to exclude the animal's head from the circuit during the rhythmic excitations, in order to exclude the medulla oblongata with the cardiac and respiratory centers and avoid any further anemia of these centers during apparent death, while the electric rhythmic excitations were being practiced. I also reduced the current to minimal doses for the first rhythmic excitations, because I found that useful cardiac and respiratory excitability was rapidly exhausted within the few minutes of apparent death. The maximum potential at the end of the resuscitation did not exceed 120 volts. Even this is too high voltage: in dogs it causes marked vagus stimulation so that the heart beats are very slow during a long period of time after resuscitation; and the wave form of the beat does not resemble the normal form. In ordinary severe cases, 70 volts is a good maximum potential.[6]

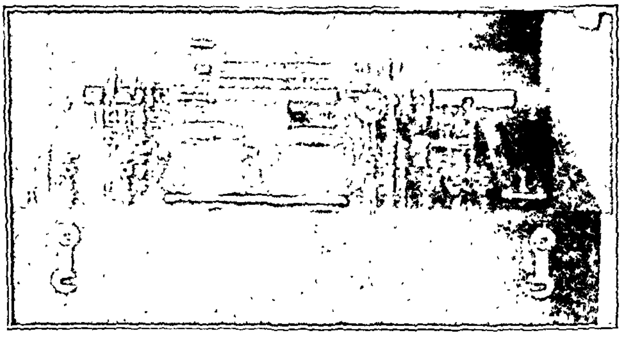

Fig. 2.—Author's triple interrupter of direct currents (20,000 to 40,000 interruptions). For resuscitation in ambulance service.

The method of resuscitation consists in causing artificial blood-pressure and respirations by means of rhythmic electric excitations, until normal function is restored. My choice electric current is the *one I use for causing* electric sleep and analgesia: a direct current, interrupted from 6,000 to 8,000 times per minute, period 1/10. Next in value is a direct current interrupted from 25,000 to 40,000 times per minute with my triple interrupter.[7] The last choice, and the one that I do not recommend if the first two can be had, is an induction current obtained with my special model of induction coil, an ordinary Dubois-Reymond coil, the special feature of which is the diameter of the wire of the coil, 1.2 mm. for the primary and 0.6 mm. for the secondary coil.[8] In cases of grave forms of apparent death, currents supplied by coils with fine wire will kill the animal, if it is not already dead.[9] Induction currents are alternating currents, the wave form of the current running above and below the base line. The physiologic effects of anodal and cathodal stimulations are distinctly different; the anodal stimulations are particularly dangerous in pulmonary and cardiac area when the current is obtained from a secondary coil, the wire of which is finer than 0.6 mm. Alternating and direct currents are deadly to cellular life, especially during apparent death.[10] But if nothing else can be had, rhythmic excitations may be practiced with these currents, rather than make no attempt to save life.

PROCEDURE

The dog's back is shaven in two places—on the back of the chest covering the pulmonary area and over the loins. The negative electrode is applied under the chest, the upper border reaching to the root of the neck. It is dangerous to use the positive pole under the chest. The positive electrode is applied over the loins. The electrodes measure 12 by 25 cm. for dogs of large size. They are made of zinc and are covered with a thick layer of absorbent cotton wet in a salt solution, 7 per 1,000. In man the chest electrode measures 25 by 30 cm.

Chloroforming is performed intensively, admitting little or no air and causing arrest of respiration and heart beats as quickly as possible. When breathing is no longer registered by the pneumograph and the manometer does not register any blood-pressure, the chloroforming is discontinued at once. An assistant catches hold of the animal's tongue with a tongue forceps, cleanses the mouth of mucus and pulls the tongue outward to allow free access of air during the rhythmic excitations.

The instrumentation with the preferred current is the same as that used for electric sleep. The operator now opens the switch of the cathode line, turns on a current of some 20 to 25 volts by means of the potentiameter. The circuit is then closed by means of the switch during a period of a fraction of a second. A deep inspiratory movement takes place. The mouth opens, the flabby, lifeless tongue that was lying on the roof of the mouth (the animal is on its back) contracts and is drawn inward; the fore paws are thrust upward with marked force; the posterior limbs are extended; the diaphragm is pushed downward and all the respiratory muscles enter into play. The chest is fully expanded and the pneumograph registers an ample artificial inspiration. The manometer may also register an artificial blood-pressure; but in cases of severe cardiac syncope the first few rhythmic excitations cause respiratory reaction without artificial blood-pressure. The operator breaks the circuit by opening the switch. This is followed by a deep expiratory movement, and all the muscles that entered into play to cause the artificial inspiration are now again flabby and lifeless; the expanded chest collapses and the pneumograph registers an ample expiration; the anterior paws fall one on each side of the body, the tongue falls to the roof of the mouth, lifeless, the mouth closes and the whole body is again lifeless and relaxed. The switch is kept open for a period of from one-half to one second, according to the gravity of the case. If the first voltage used caused an ample respiratory reaction and the manometer showed a momentary rise of blood-pressure, the succeeding rhythmic excitation is caused with the same voltage, but as a general rule it is necessary to increase the current to 30 volts or more; the excitations are now practiced with the increased current, the aim being to obtain ample respiratory reaction and blood-pressure with this minimal voltage within the shortest possible time, because useful cardiac excitability is quickly exhausted during apparent death. It is generally necessary to increase the current to 35, 40, 50, 60 and 70 volts within the course of three or more minutes of apparent death; the excitations are being practiced while the voltage is being increased. In favorable cases ample respiratory reaction and artificial blood-pressure are soon established, then accompanied by feeble spontaneous respiratory and cardiac reactions; these soon increase in amplitude; they are alternated with ample artificial reactions if necessary, taking care not to encroach on the spontaneous heart-beats and respirations, but rather precede or follow them. The operator judges by the spontaneous cardiac and respiratory reactions when it is advisable to discontinue the rhythmic excitations. If they are discontinued too soon death may set in after resuscitation, because in chloroform poisoning the blood is asphyxiated, dark; the feeble respirations and heart-beats may not be sufficient to cause useful oxygenation of the blood. But once ample spontaneous reactions are established the carotid artery is tied, the wound closed and the animal lives without showing any ill effects. I have kept such dogs during a period of one year and longer after resuscitation; they were in excellent condition.

LIMITATIONS

The period of apparent death is short; four minutes (including the time of the rhythmic excitations) is a long time, and five minutes is an exceedingly long period. But once resuscitated, the animal lives and shows no after-effects.

In chloroform poisoning death may take place in various ways: by respiratory arrest and final cardiac failure. This is the usual form; by primary cardiac failure;[11] this is a rare form in dogs, but quite familiar to surgeons in human beings, by simultaneous cardiac and respiratory arrest. In the majority of cases death sets in by respiratory paralysis, followed by cardiac failure. The accompanying tracing (Fig. 3) shows the usual form of apparent death from chloroform and the mode of resuscitation by means of electric rhythmic excitations with a gradually increasing current. The amperage cannot be read in these experiments because the closures are too short, but there is generally between 4 and 40 milliamperes, corresponding to the currents used—20 and 70 volts. This amperage is obtained on dogs sacrificed for this purpose, so that the closures may be prolonged.

[11] The tracings of resuscitation after primary cardiac syncope from chloroform and ventricular tremulation caused by electrocution are omitted here for want of space.

Electrocuted dogs are resuscitated less easily than are chloroformed dogs. It is especially difficult to resuscitate when ventricular tremulation sets in, but the tracing that I present[11] shows that resuscitation is possible even in this condition.

All experimenters on this subject agree that artificial respiration and the Sylvester method are useless when ventricular tremulation sets in.[2, 3, 12] My method seems to give the best results known to-day for practical application, because it produces ample artificial blood-pressure as well as respiration.

APPLICATION IN ACCIDENTAL ELECTROCUTION

According to personal information given me by practical electricians both in Europe and this country, death does not always take place instantaneously in accidental electrocution with moderate industrial currents. The workingman generally touches the "live" wire with his hand or foot; contact is generally "bad," but it is sufficient to cause cardiac and respiratory paresis, from which the patient may die within from a few minutes to one-half hour after the accident. These are facts observed in daily accidents, regardless of some experimenters' claim that all is well if the patient's heart beats and he breathes when taken out of the circuit.

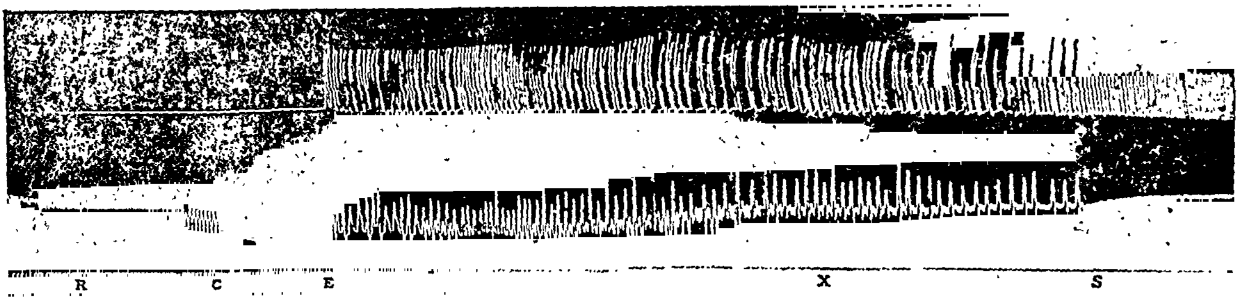

Fig. 3.—Tracings made during usual form of apparent death caused by intensive chloroforming in a dog. Upper tracing, respiration; second tracing, blood-pressure in carotid artery; third tracing, time; two lines indicate one second, during cardiac failure only. In rest of tracing: one line indicates one second. *R*, respiratory syncope; *C*, cardiac syncope; *E*, commencement of electric rhythmic excitations (direct current interrupted 8,000 times per minute, period 1/10); gradual increasing current from 20 to 65 volts. The ample respiratory and cardiac reactions are artificial, caused by the rhythmic excitations; then the small spontaneous heart-beats appear and alternate with the ample artificial ones. The cross shows where the first small spontaneous respiration appeared; ample artificial respirations alternate with the small spontaneous ones. *S*, synchronous respirations and heart-beats; final resuscitation.

The blood is asphyxiated, dark, after the slightest shock; a few rhythmic electric excitations will help to whip up the circulation and respiration if the excitations are practiced immediately following the accident or as soon as possible—before the patient is removed to a hospital. Without this help the patient may die when he is brought into the ward—some half hour after the accident. The blood remains asphyxiated even after resuscitation. This asphyxia may continue during many hours.

APPLICATION IN SURGERY

Direct and indirect cardiac massage has claimed its victims of chloroform poisoning in surgical work.[13] Dr. Crile's method of resuscitation is brilliant and admirable as regards the range of time during which the heart's action may be restored. Unfortunately, his method presents physiologic limitations; resuscitation after a period of seven minutes (in man), counting from the time of cardiac arrest, becomes useless, because the anemia of the brain during this time is fatal to the life of the brain cells; restoring heart action becomes useless from the point of view of restoration of life.

My method has the great advantage of simplicity; it does not necessitate opening the carotid artery and injecting a pint or so of solutions into the heart; it does not necessitate opening the trachea. The method may be applied immediately, when the first sign of cardiac or respiratory failure appears. Before an operation is commenced the electrodes may be put in their proper places under the patient; the chest electrode (25 by 30 cm., the loin electrode (12 by 25 cm.). The apparatus and chosen electric source should be in readiness before the operation is commenced.

The accompanying tracing (Fig. 3) shows that it is possible to resuscitate dogs after respiratory and cardiac function is no longer registered during a given period of time. It should not be assumed, however, that resuscitation is easy in all grave cases. There are not two subjects alike as regards physical vitality. For practical application in surgery the safest method is to commence practicing rhythmic electric excitations at the first sign of respiratory or cardiac failure. The surgeon does not fold his arms and wait until both the respiration and the heart have failed. In a series of experiments on dogs I commenced the rhythmic excitations a few seconds after respiratory syncope set in—in imitation of what a surgeon would do if he had a patient showing signs of syncope from chloroform or ether. Resuscitation was easy and complete in these experiments after a few rhythmic excitations. Resuscitation is more difficult, of course, when heart failure dominates the accident.

Considered in its proper light, the method should really serve as a preventive measure against grave forms of syncope, because a few rhythmic excitations, practiced in time, promptly oxygenate the blood by reason of the ample respiratory and cardiac reactions.

CLINICAL APPLICATION

November, 1908, I had occasion to revive a patient in a condition of profound syncope caused by chronic morphin poisoning. She was in Dr. Magnan's service, Ste. Anne Asylum, Paris. Dr. Magnan had revived her after she had had a first attack of syncope. A second attack

[13] White, Charles S.: The Rôle of Heart Massage in Surgery, Surg., Gynec. and Obst., October, 1909.

set in within a few minutes; his assistants attempted to revive her by applying the Sylvester method and rhythmic traction of the tongue; this proved useless during a period of twenty minutes. The patient's face became "blue" from asphyxia. As is known in morphin poisoning, the respiratory center is paralyzed first, heart failure following, as is the case in ordinary asphyxia. The patient's respirations were about 3 or 4 per minute; the pulse was hardly perceptible and death seemed to be imminent. I applied electric rhythmic excitations; the patient revived definitely after a period of from twenty-five to thirty seconds.[8, 14]

OPERATION FOR RETRODISPLACEMENT OF THE UTERUS*

J. M. BALDY, M.D.
PHILADELPHIA

I am not greatly interested in the minute anatomy, the exact relative normal position of the organ and ligaments when I am faced with a displacement of the uterus. There are so many factors entering into the new position, and so much uncertainty as to which one or which combination causes the trouble that the question to be solved is rather, how the uterus can be held in such a position as to relieve the untoward symptoms and at the same time do no future damage. It matters little to us whether the means used are the natural ones or not. As a matter of fact, this is exactly what is done by each and every operator without exception, no matter how learnedly in the first instance he discusses the natural supports.

In further discussion I shall merely present the procedure, with which I have been experimenting for the past twelve years or so, which is, I think, fully established and amply justified by results, and which has taken the place of all other procedures in my practice for this class of cases.

The operation is not new. I first referred to it in a paper in 1902 after a few years' trial only. I have performed it almost constantly ever since, modifying it here and there at times as apparent difficulties arose and as it seemed necessary to overcome certain objections and certain faults in results; and I find at the present time a completed technic which is, I think, perfect.

Primarily the operation was done empirically with no idea of its true mechanics; and, this being so, it may readily be appreciated why apparent difficulties were hard to overcome and why changes were necessarily but blindly made from time to time. And yet, with it all, the general principles have remained the same from the first, viz., "the round ligaments brought through an opening made in the broad ligaments and united behind and to the uterus." The proposition is simple, the resulting advantages being manifest only when the procedure is properly carried out. The mechanism is plain, but has never to my knowledge been fully appreciated or fully pointed out, even by Webster, who has for the same length of time performed an operation with exactly the same principles but varying slightly in technic.

What is the position and condition of the uterus in the normal female pelvis? The fundus is bent slightly on the cervix and well forward of the direct axis of the pelvis, it is freely movable in all directions within certain well-defined limits, moving always with the cervix as a movable pivot. The whole organ is so high in the pelvis as to allow the top of the fundus to arise well above the iliopectineal lines of the bony pelvis. The ovaries are suspended correspondingly high and rest on the upper posterior portion of the broad ligaments. Any operation which does not take these conditions fully into consideration and which does not leave the organs approximately in these conditions and positions cannot be considered as ideal.

In all the confusion of anatomy, physiology and pathology, sight is lost of the fact that in the vast majority of cases there is a general relaxation and stretching of all the supports, often of the whole of the abdominal contents, and that the uterus as well as the ovaries lie down, as it were, in the pelvis limp and inert; the stretching of the ligaments is that of overstretched rubber, not that of hypertrophy of tissue which may subsequently undergo involution. The loss of support is a complex one, not merely the defect of one ligament; and the ratio of loss in each individual element of support is impossible of estimation, nor is it worth while to try to estimate it. The point is not to tell just what is the degree of relaxation of one of the uterosacral ligaments or both, what that of the right uterovesical ligament or both, or what that of the broad ligaments, and then to attempt to devise an operation for each and all these supposed defects, but to recognize the fact that before us is a group of organs which for some reason or other (it matters not what) are in a false position and being so are exposed to traumatism and other influences which will eventually or have already brought about a train of symptoms which it is very desirable to abate. These organs having lost the use of their natural supports, can we successfully substitute others to take their place? These are the lines on which I have worked most successfully and this is the basis of the accompanying operation. The round ligaments are used as artificial supports in an artificial manner to accomplish

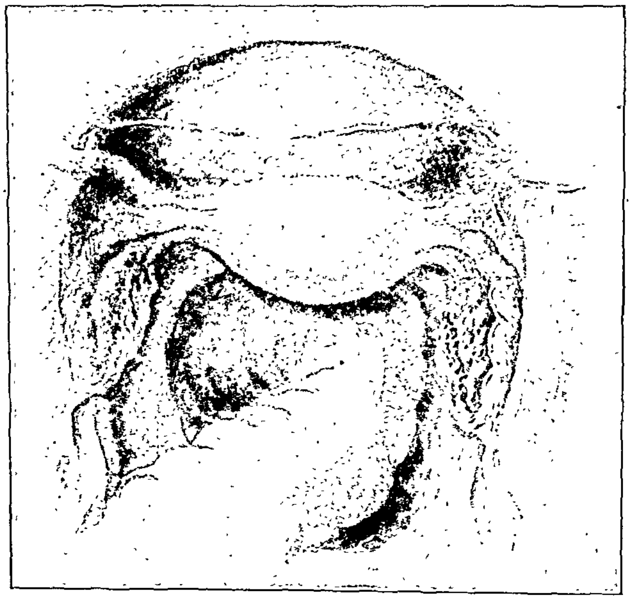

Fig. 1.—Uterus and appendages low in the pelvis and inclined backward. This is brought out more clearly by contrasting Figure 1 with Figure 2, in which one side is raised by the fingers well up above the iliopectineal lines while the opposite side remains low down in the pelvis.

---

[14] Robinovitch, Louise G.: Resuscitation of a Woman in Profound Syncope Caused by Chronic Morphin Poisoning, Jour. Ment. Path., 1909, viii, No. 4.

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

what Nature originally accomplished, viz., "a uterus with the fundus forward of the direct line of the axis of the pelvis, freely movable in all directions on the cervix as a movable pivot, the fundus raised up to and above the iliopectineal lines and the ovaries swung correspondingly high and free from all attachments on the posterior side of the broad ligaments." The simple procedure of drawing the round ligaments around the posterior side of the uterus, fastening them together as they meet, and then fastening them to the uterus itself at a selected point, fulfils perfectly each and every one of these indications.

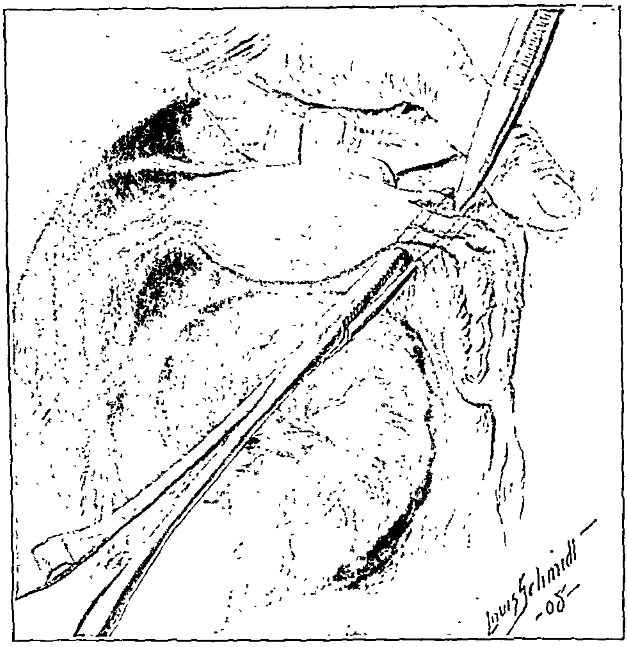

Fig. 2.—Fundus drawn well forward and away from the sigmoid flexure; hemostatic forceps perforating the broad ligament from behind to its anterior aspect, on which lies the round ligament. A pair of tissue forceps is grasping the round ligament and carrying it into the bite of the perforating hemostatic forceps.

A study of the accompanying illustrations, which were drawn at the operating-table, will render the operation and its results perfectly clear.

Contrast Figure 1 with Figure 5 and note the following points: the distance from the fundus to the sigmoid, the distance from the fundus to the pubis, the height of the fundus and ovaries as shown by the shadows and the iliopectineal lines; also the uterosacral ligaments.

It will readily be recognized how well forward of the axis of the pelvis the fundus is brought, how high it rises in the pelvis and how high are the ovaries and Fallopian tubes.

The question at once arises: What forces are brought into play to bring these organs into such perfect position and how do they act to retain them there?

The uterus is upheld by the encircling round ligaments (Fig. 5, *a-b*).

The ovaries and Fallopian tube are upheld by the passage of the round ligaments under the ovarian ligaments (Fig. 5, *d*).

The uterus is held forward by three forces, viz.:

1. The pressure of the intra-abdominal force on its posterior aspect.

2. The resistance of the encircling band of round ligaments (Figs. 7, 8, *B-C;* Fig. 5, *a-b*).

3. The pull forward and downward of the round ligaments at their attachment at the uterine cornua (Figs. 5 and 8, *b;* Fig. 9, *A*).

The whole structure is steadied by those portions of the round ligament running to the normal abdominal attachments (Fig. 8, *A-C;* Fig. 5, *a-c*).

It will be noted by reference to the illustrations (Fig. 2) that the forceps perforate the broad ligament close to the uterus and directly under the ovarian ligament. This is essential to the best results. A too low perforation in the broad ligament will give an unsatisfactory result. When the round ligaments are adjusted and brought snugly together posteriorly the ovarian ligament rests on each round ligament and, without so much as touching the ovary or Fallopian tube, always and with absolute certainty insures the proper and safe elevation of those organs. This is the only operation of which I know that secures this result; and if one recognizes the truth that it is often the prolapsed ovary which induces the symptoms, one must readily recognize the great advantage of this. When the uterus is thrown forward by almost any other operation, the ovary will usually rise in the pelvis with it, and the displacement of the two organs will be corrected at one and the same time. But every operator will recognize the fact that there is a certain large group in which the ovarian ligaments are relatively more stretched than those of the uterus, and in spite of the fundus being brought forward the ovaries are still prolapsed.

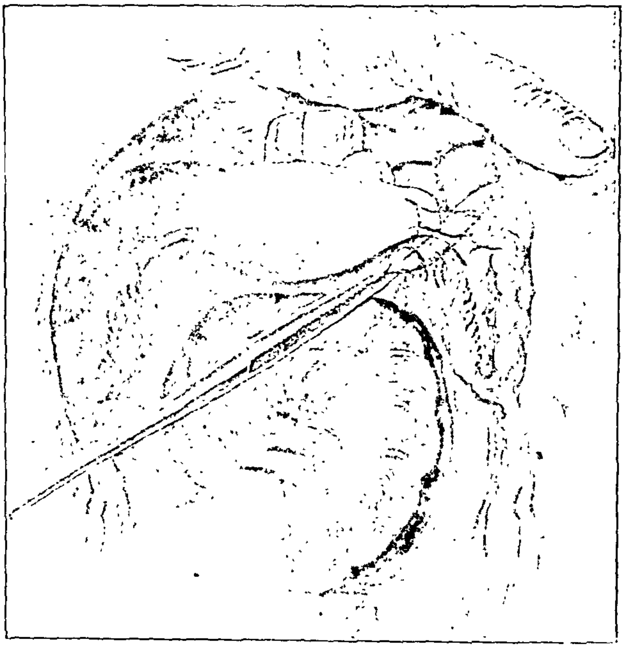

Fig. 3.—Round ligament in the grasp of the hemostatic forceps and in process of being drawn through the broad ligament to its posterior aspect.

The elevation of the ovaries is not accomplished by the general elevation of the uterus alone, but is materially aided by the rolling forward a quarter of a circle or more of the top of the broad ligament owing to the pull backward of the round ligament as it passes through the hole in the broad ligament, and the more the posterior pull of the round ligament the greater the tendency to the rolling forward of the top of the broad ligament and the consequent elevation of the ovary and Fallopian tube. I have in no case seen this occur to such an extent as in any way to endanger the patency of the tube. This whole mechanism is perfectly plain when seen in the living subject and is perfectly compatible with every known mechanical law.

The second fact accomplished is that of the elevation of the uterus and everything connected with it (Fig. 5). This is brought about, of course, on principles somewhat similar to those which would be involved in grasping a boy in one's arms and lifting him up. This requires fixed points from which to act. In the operation these points are the attachment of the round ligaments to the abdominal wall, their attachments to the fundus uteri, their attachment throughout their whole course through the broad ligaments, and, finally, the artificial attachments made by the operator as they are brought together behind the uterus and stitched to that organ.

It has been said in criticism that the round ligaments will be stretched by the weight put on them and that the weakest part of the ligament, viz., the abdominal wall end, is the part which carries the whole weight. Only ignorance of the mechanics and the fact that the critic has not performed the operation can justify this criticism. If it be contended and believed that the weight of the uterus and pelvic organs can be sustained by the longitudinal pull on the round ligaments, as is the case in the Gilliam, the Mayo, the Montgomery, the Alexander and every other modification of this class of pure suspension operations, in how utterly prejudiced a condition must be the mind which fails to grasp the fact that the downward pull of the organs against the lateral resistance of the full length of the ligament has only a fraction of the chance of overstretching which obtains in the longitudinal pull! In the operations of the class just mentioned, pure and simple suspension operations all of them, the full success of the result depends entirely on the suspension, not another element entering into the result. Furthermore, in these operations one and all the pelvic organs are lifted by sheer force into the abdominal cavity, there to be suspended in a position they were never intended to be, with lessened mobility and the full weight of the downward drag, permanently dependent on the integrity of the round ligaments alone.

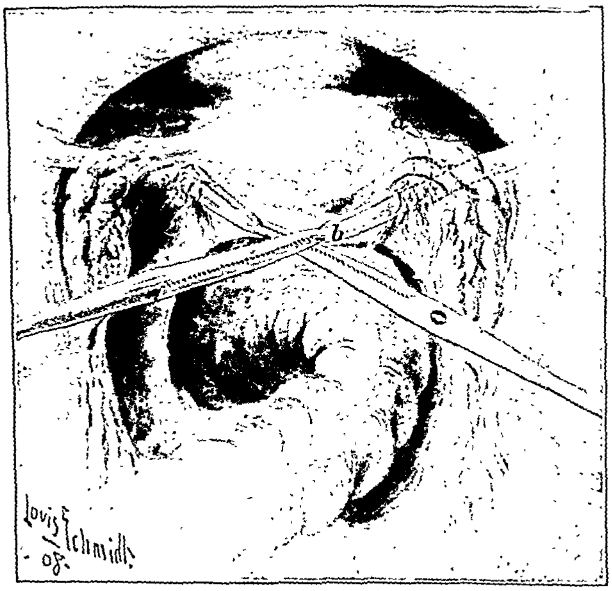

Fig. 4.—Both round ligaments drawn to the posterior portion of the broad ligament and approaching each other.

Contrast this condition with the operation under consideration. The uterus is lifted up and sustained by the encircling round ligaments as shown in Figures 6, 7 and 8. But only temporarily is this full force put on the round ligament. The fundus is thrown forward of its center of gravity, and as the patient lies on the operating-table with the abdomen open the fundus remains forward where the hand places it (Fig. 5). In this position the intra-abdominal force is exerted on the posterior aspect of the fundus, forcing it the further forward and the more surely holding it there. Gravity also aids this action.

What occurs when the patient arises? On certain movements the fundus has a tendency to go backward. Should this occur the intra-abdominal force would soon be exerted on the anterior aspect of the fundus and the uterus would be forced to a posterior position.

In studying the mechanism of the forces at play it is soon evident that two things prevent this accident.

1. The sling back of the uterus formed by the round ligaments properly adjusted meets the force temporarily urging the fundus posteriorly and obstructs that action.

2. The force of the fundus against the encircling round ligaments causes a pull on the ligaments at their attachments to the anterior uterine wall; and the harder this pull the greater the tendency to draw the top of the fundus forward and downward and to antagonize the tendency backward.

In other words, we have two forces acting against and neutralizing the efforts of the uterus to go backward, and it is impossible for the one to be brought into play without the other instantly operating to aid it.

Until some effort of the individual causes the situation to arise which attempts to force the uterus backward, the uterus remains quietly forward by combination of gravity and intra-abdominal force, and no tension whatever, other than that which is being exerted to uphold the uterus, is put on the round ligaments. In other words, for the most part there is no pressure exerted on the round ligament at all; it is only called on intermittently and temporarily to exert itself and when it does so at all it offers two points of resistance: in the obstruction posteriorly and in the pull forward and downward

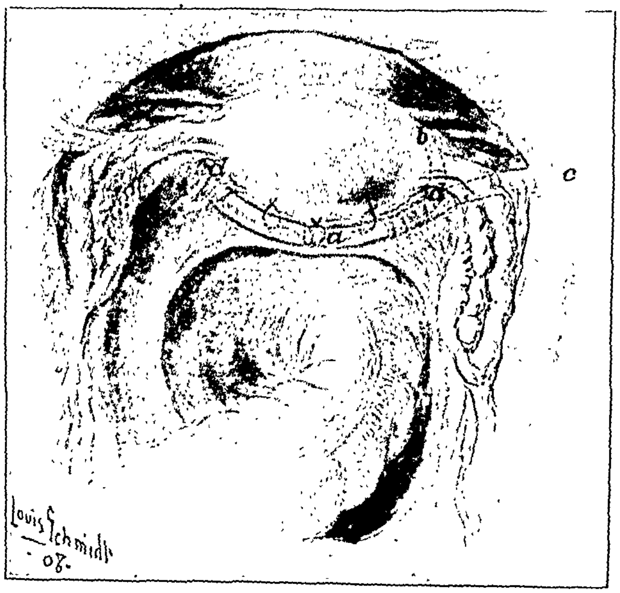

Fig. 5.—The two round ligaments united to each other, and, at two points, to the uterus itself; the operation is completed.

at the uterine cornua, thus subdividing the work put on it.

In all the suspension operations, without exception, the full weight of the pelvic organs are permanently dragging on the normal ligaments in the most vulnerable direction. Those parts of the round ligament running to the abdominal walls are only slightly affected in this operation; they act mostly as guy-ropes to the whole structure, as similar ropes act in holding up a derrick, and in this operation brought into action only intermittently and temporarily. There is therefore absolutely no chance of their becoming overstretched, as has been suggested. At one time in the process of the evolution of the operation I severed these ends and did not use them at all, so little did they seem to enter into the mechanism.

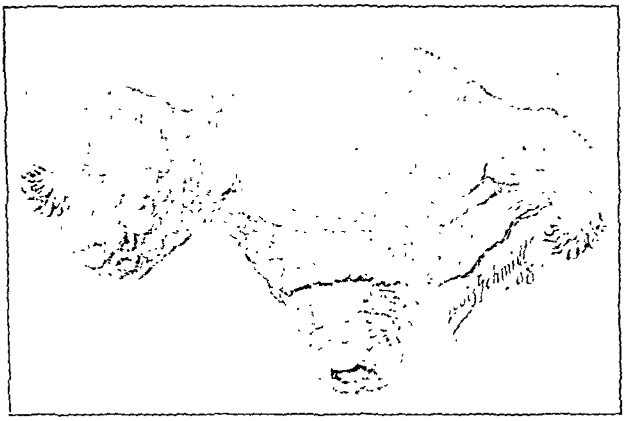

Fig. 6.—Uterus removed by amputation one year after operation for displacement, the symptoms not having been relieved. The round ligament can be plainly seen encircling the uterus and attached to that organ.

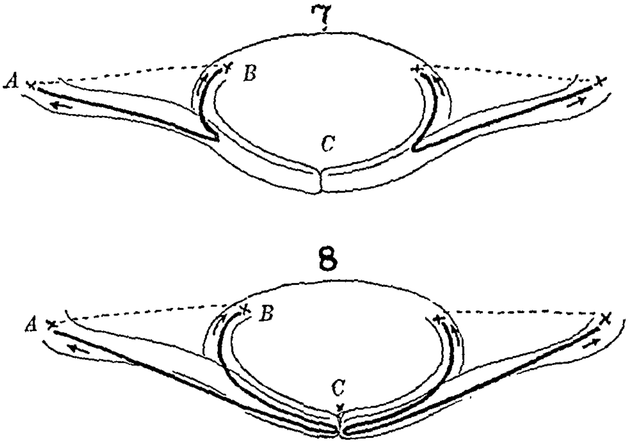

Figs. 7 and 8.—Diagrams showing the ligaments partially and completely drawn in place, as is done in the operation.

For a full understanding of these important forces, study Figure 9. This represents a lateral section of the uterus, broad ligament and appendages. Take the diagrammatic lines *A, B, C.* When force is exerted on *C* backward (as would be the case if the uterus were forced back against that point) the effect on *A* will be downward and forward, provided *B* be a fixed point. A mere glance at the diagram and the line of the forces makes this clear; it is purely a question of mechanics.

In the operation point *C* of the diagrammatic line is represented by the point of artificial attachment of the round ligaments on the posterior part of the uterus (Fig. 5, *a*).

A in the diagram is represented by the natural uterine attachments at the cornua of the uterus on its anterior face (Fig. 5, *b*).

B, in the diagram, is represented by the ovarian ligament, which is relatively a fixed point (Fig. 5, *d*).

Although the ovarian ligament is not an absolutely fixed point, yet it is sufficiently so to supply the point of fulcrum and produce the result pointed out.

The moment the uterus attempts to leave its forward position it meets the resistance of the obstruction of the encircling ligaments as well as the forward and downward pull at the anterior cornual attachments. It thus rides in a cradle as it were, movable backward and forward without ever being able to get back beyond its center of gravity or posterior to the direct line of axis of the pelvis. Hence the third force at play (the intra-abdominal force) is constant in its pressure on the posterior aspect of the uterus and thus trebly insures a permanent result. But one possible thing can happen to spoil the operation, viz., the complete breaking down of the suturing, which is so simple as to make that accident inconceivable.

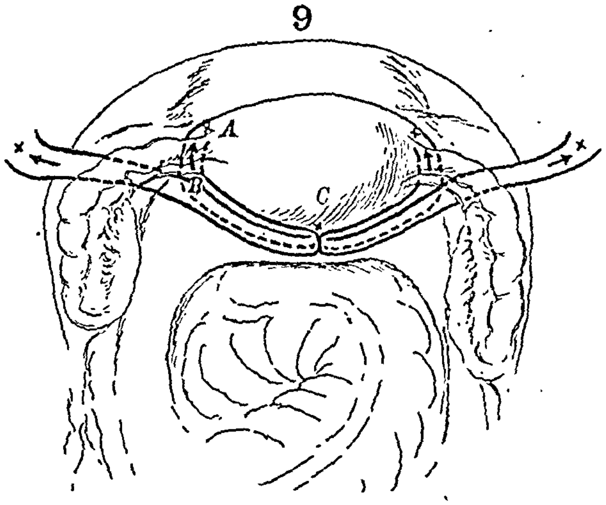

Fig. 9.—Outline sketch showing forces brought to bear and their results after operation is completed. When force is exerted on *C* backward (as would be the case if the uterus were forced back against that point) the effect on *A* will be to draw it downward and forward, provided *B* be a fixed point.

In adjusting the ligaments as they are brought together back of the uterus care must be taken first to draw the inner circle of the doubled ligaments (Fig. 4, *a-b*) snugly about the uterus as the organ is held in a good anterior position by the hand. They are then sutured together by a single stitch. The last step is to fix the loop to the uterus by a stitch or two at a point which will insure its anterior position. It is best not to make the attachment at a point higher than necessary to secure an assurance that the fundus cannot double backward over the encircling round ligaments. This point is found with little difficulty. If this precaution is not followed, the result may be unsatisfactory.

Care of the Insane.—Proper treatment and nursing of the acutely insane call for the broadest intelligence, not only on the part of the physician, but also on the part of the nurse and all who are brought into immediate contact with the patient.—W. K. Walker, in *Pennsylvania Medical Journal.*

ROUND-LIGAMENT VENTROSUSPENSION OF THE UTERUS *

D. TOD GILLIAM, M.D.
COLUMBUS, O.

As everyone is probably aware, this is the original ventrosuspension of the uterus in which the ligaments are left intact and in which the peritoneal investment is not disturbed. In devising this operation I wanted to get something that was as nearly physiologic as possible—something that would meet the requirements, without the drawbacks incident to the methods then in vogue. Especially was I anxious to get away from all fixations, as they are inherently pernicious and often fraught with disastrous consequence. The uterus is a mobile organ and cannot be fixed in any position or agglutinated to any other organ without detriment to itself and to other organs and parts which are contiguous or correlated. It must conform to various conditions of the bladder; it must alter its position according to the fulness or emptiness of the rectum; it must yield to the impulses of respiration and adjust itself to the various movements of the body. Unless it does so, it will impinge on, or be impinged on by other viscera and both will suffer. But this is not the worst. The paramount functions of the uterus are those essentially related to the great act of reproduction—pregnancy and parturition. The bound-down uterus cannot accommodate the growing fetus and the result, in many instances, is its premature expulsion. Should the fetus go to term, as it sometimes does, fortunately or unfortunately, it will be at the expense of unequal uterine development, distortion, changed axis, unbalanced muscular action and ineffectual expulsive effort. Such conditions at the accouchement always create consternation and too often culminate in disaster.

I shall not attempt to discuss the still mooted question as to what are the essential supports of the pelvic viscera, but there is one thing in which everyone agrees, and that is the necessity of having an intact pelvic floor to keep the viscera from settling. The first essential, then, toward correcting the backward displacement of the uterus is to restore the pelvic floor and the next is to replace the uterus and keep it there. The only way to keep it in position without compromising its usefulness is to utilize its natural guys—the round ligaments. Recognizing this fact, Alexander devised the operation of shortening the round ligaments at the inguinal outlet, and this is the basic principle of all modern operations for anchoring the uterus; but the Alexander operation makes no provision for the adherent, retroverted uterus, the condition most frequently calling for operation.

The caption of this paper signifies a suspension of the uterus from the abdominal wall by means of the round ligaments. This is a palpable misnomer, as will appear later, but was used as the most eligible term to express an approximation to the truth. Suspension of the uterus is neither rational nor feasible. None of the ligaments of the uterus, even the strongest, acts as a suspender of the uterus under normal conditions. A view of the uterus and its ligaments *in situ* will make this clear. The ligaments are all on practically the same plane with the uterus and lax; consequently, they cannot exert any suspensory influence. Should the uterus settle in the pelvis, or draw away from its moorings so as to assume a lower plane and put the ligaments on a stretch, they may, in a measure, become suspensory, but they soon prove their inefficiency by yielding to the sustained traction and thereby become of little value in a rôle for which they were never fitted. These little cords, like all the other uterine ligaments, are lax and allow of considerable latitude of motion backward and forward, but exert a gentle influence to prevent the organ from passing the vertical line. A slight resistance on the part of the round ligaments is ordinarily sufficient to check the backward movement of the uterus when, with the changed position of the body or the movements of respiration, the organ falls forward into normal anteposition. This, then, was the principle on which, as I believed, the solution of the question depended, and it was along these lines that the operation was devised. The fact that there have been a number of modifications of the original operation only serves to emphasize the strong probability that the principle is right and that round-ligament ventrosuspension, in one form or an other, has come to stay. Of these modifications, all of which are good and some excellent, I shall not speak, as they are each and all sustained by men of ability who are able to take care of their own. What I desire especially to accentuate in this paper and to reiterate, is the simplicity, safety and efficiency of the original operation, and its freedom from unpleasant sequelæ.

OBJECTIONS

The principal objection urged against the operation as originally devised was the danger of intestinal obstruction. This was brought forward early in the history of the operation, but of late I have heard nothing of it. That the objection was based on theoretical grounds entirely and not well founded is made manifest by the crucial test of time and numbers. Thousands of cases, during a period of more than a decade of time, have failed to furnish a single authenticated case of intestinal obstruction due solely and intrinsically to the operation.

The objection has also been advanced that after parturition the ligaments fail to exert any restraining influence over the uterus and that that organ reverts to its original malposition. This is true, but in a temporary sense only, just as it is true of many other uteri which have not been misplaced before, and is due to the size and weight of the uterus and elongation of the ligaments—not only the round, but all the ligaments which tend to hold the uterus in place. It is not only the uterus which develops during pregnancy, but the ligaments, the vagina, and all the soft parts of the pelvis, so that immediately and for some time after delivery, the pelvic cavity is more capacious and there is not the snug relationship of organ to organ which exists in the normal unimpregnated state. In operations during pregnancy, I have seen the round ligaments greatly elongated and of a thickness equal to that of the little finger. After involution of the uterus, the ligaments and soft parts has taken place, it will be seen that the uterus has returned to its normal position and that the round ligaments are as efficient in keeping it there as before.

Again, it has been objected that the operation is too apt to be followed by suppuration. There is not force in this objection. It has been many years since I had a suppuration following round ligament ventrosuspension. True, in the beginning I had cases of suppuration, some of a most aggravated type, but as I became familiar with the manipulative details, learned to deal with the tissues gently, and acquired that automatic asepsis that comes with practice, then suppuration ceased and with it the concern for suppuration. Suppuration following this operation means the same as in any other, neither more nor less.

ADVANTAGES

Having disposed of the objections to the operation, I wish now to emphasize and reiterate its advantages. The cardinal virtues of this operation are to be found in its simplicity, safety, facility of execution and efficiency. It is so simple that any one of ordinary intelligence can understand it, and any one of ordinary surgical training can do it. It is so safe that any untoward result from it is almost inconceivable. The operation can be done with such ease and facility that with ordinary surgical skill and care there should be no question of infection or exhaustion. On this account it is especially valuable in multiple or combined operations in which it scarcely appreciably adds to the risk.

As regards its efficiency, I have never known a failure in a properly selected case in which the work was properly done. I have had one failure in my own practice; I attempted to anchor an anteflexed and retroverted uterus, held low down in the pelvis by a rigid and unyielding pelvic diaphragm, such a uterus as one occasionally finds in the virgin, which is not amenable to treatment of any kind. In such a case the operation should never be attempted. Neither should it be attempted in any case in which the uterus and appendages cannot be freed so as to allow the uterus to occupy its normal position without tension or restraint. Such cases are, however, extremely rare. Another cause of failure, as I have observed, is careless suturing of the ligament. Occasionally the ligament is not transfixed by the suture, when appearance would indicate that it had been. This is owing, in part, to the constriction of the ligament where it passes through the abdominal parietes. In order to be sure that I have the ligament on my needle, I direct my assistant to relax traction on the ligament while the needle is *in situ,* when, if the ligament does not retract, I know I have it on my needle. I have had occasion to remove the uterus at different periods after round-ligament ventrosuspension, and have always found the ligaments firmly attached to the abdominal wall and not yielding to any traction which I was willing to exert on them. As regards pregnancy and parturition after this form of suspension, I have found not only no evil results, but actual improvement in conditions owing to the uterus being held in the normal position. Cases of this kind are now too numerous to require special mention. While the technic is quite generally understood, the fact that I still occasionally get letters of inquiry with reference to certain points connected with it, suggests to me the desirability of again publishing it in this connection.

TECHNIC

The peritoneal cavity is entered by an incision at the usual site between the umbilicus and pubes. Adhesions are broken up and the fundus brought forward. By lifting up the anterior surface of the broad ligament on one side on the tip of a finger applied to its posterior surface, the round ligament is brought into view and picked up either between the thumb and finger, or with a bullet forceps.

Selecting a point an inch and a half from the uterus, a thread is passed under the round ligament (with its peritoneal investment) and the ends of the thread are brought out of the opening and secured in the bite of a clamp forceps which is laid on the surface of the abdomen. The other ligament is sought for and secured in the same manner.

At a point about one inch and a half above the pubes, the peritoneum, muscle and fascia on one side of the wound, are caught up by a volsella and pinned together, care being taken that the edges of these layers are in line. Traction is now made with the volsella and, with a claw retractor, the skin and superficial fat are drawn in the opposite direction, and with a sweep of the knife the face of the fascia is cleared. With a slender-nosed forceps, or better with a Cleveland ligature-carrier a stab wound is made from the surface of the fascia into the peritoneal cavity. This wound is one inch from the edge of the incision and about one inch and a half above the pubes. The jaws of the forceps are separated so as to make the opening large enough to permit the ligament to be drawn through it, then by depressing the handle the jaws are brought into plain view at the abdominal opening. The thread which loops the round ligament is now placed in the jaws, the clamp forceps and the perforating forceps removed, the latter bringing with it the thread and the ligament. Now, while the ligament is held taut with the loop end a quarter of an inch above the surface of the fascia, a catgut suture is passed through it including the tissues on either side, and back again where it is tied. This is cut close to the knot, the suspending thread cut on one side close to the ligament and withdrawn and the volsella and retractor removed. The other side is dealt with in like manner and the abdominal incision closed.

After both ligaments have been fastened it will be seen that an opening exists between the uterus and abdominal wall of from 7 to 9 inches in circumference, thus obviating any possibility of strangulation of the bowel. It will be observed that the uterus is not suspended but rests easily and naturally on the bladder, from which it can be raised to a position little short of the vertical. Thus the uterus is enabled to conform to the altered conditions of the bladder and rectum and to the various bodily movements. Should pregnancy ensue the ligaments develop *pari passu* with the growth of the uterus and there is neither embarassment in gestation nor difficulty in parturition.

IN PROLAPSUS

The application of this principle to prolapsus uteri is a thought of later years. Sacrifice of the uterus as in vaginal hysterectomy, does not always secure immunity from secondary prolapse of the vaginal walls, bladder or rectum. The Watkins-Wirtheim operation, while elegant and most satisfactory in the main, is applicable only to post-climacteric cases. This operation requires such extensive dissection of the bladder wall that many are loth to undertake it. Uterus fixation is temporarily, at least, very satisfactory, but cannot always be relied on for staying qualities. Most of the other methods which have been proposed for this condition are obsolete. A few years ago I conceived the idea of using round-ligament ventrosuspension of the uterus with certain modifications in prolapsus uteri, and although I have used it only a few times, the results so far have been eminently satisfactory—more satisfactory than with any other method of which I have knowledge. The steps of the operation are exactly those of the ordinary round-ligament suspension with the difference that the round ligament is first drawn through the broad ligament by means of perforating forceps and the thread which is looped around it and then taken up through the abdominal wall by the same thread and in the manner already described. Of course, the pelvic floor is to be repaired as in other operations and occasionally it will be found of advantage to amputate the cervix. The patients on whom I operated suffered from aggravated complete procidentia and today they are in excellent condition with a sense of perfect comfort and well-being so far as the pelvis is concerned. I suggest it as a simple and effectual method of dealing with a very troublesome condition.

THE EVOLUTION OF THE SURGICAL TREATMENT OF RETRODEVIATIONS OF THE UTERUS *

E. C. DUDLEY, M.D.
CHICAGO

I desire at the outset to enter a disclaimer, in that I believe that the surgical treatment of deviations of the uterus and associated pelvic organs is far from settled, so far that perhaps some of the hysteropexies, the ligament shortenings, the suspensions, the fixations, in their wide divergence may to the next generation look as crude and unscientific as the routine clamp and drainage-tube in ovariotomy now look to us. Perhaps we are a little too inclined prematurely to dogmatize on the subject—and especially the inventor of an operation is like the expert witness, who said: "Your honor, in matters of fact I am often mistaken, but in matters of opinion I know I am right."

The fine adjustment of the mere mechanical technic of any or all of the current operations is of less consequence than the selection of suitable cases and the recognition of the facts that surgical measures are not demanded for all retrodeviations; that there is no fixed normal position of the pelvic organs; that the matter is one rather of normal movements than of normal position; that the normal supports, so-called, are functionally concerned, not with holding the organ in some fixed position, but rather with restraining it within its normal range of movements; that a uterus out of place, if you please, may by a surgical procedure be put in place and so fixed that the fixation is more injurious, more embarrassing than the displacement.

Many would say, not without reason, that we all are prone to treat this subject from purely mechanical points of view and thus to lose sight of essential pathologic changes which have produced mechanical deviations, treating effect instead of cause, like damming up a river to prevent its waters from flowing into the ocean. But on the other hand we must not forget that if the resources of Nature have been exhausted in the production of the lesion we may have recourse sometimes to mechanical measures, irrespective of the fact that if an ideal anatomic and physiologic cure is impossible yet a symptomatic cure may be desirable.

Confining the discussion to the relative merits of those procedures which now have the support of progressive surgery we may classify them under two heads:

1. Operations which give sustaining power by means of peritoneal adhesions or fixation.
2. Operations which give sustaining power by shortening of ligaments.

In the interest of brevity we may disregard surgical operations of whatever class which are performed by vaginal section, not that we should condemn vaginal hysteropexy *in toto,* but that the field is relatively narrow, and the discussion therefore in this place in some degree unprofitable.

The different procedures, therefore, so far as I shall weigh them, narrow down to operations performed through the median or nearly median abdominal section.

Touching the class of operations which give sustaining power by seroserous adhesion or fixation, that is, ventral suspensions and ventral fixations, some will remember thirty years ago when it was a vexed question what to do with a retroverted uterus before closing the abdomen after a pelvic operation, such for example, as the removal of pus tubes. Sometimes cautiously and tentatively and with some misgivings, having a pioneer respect for the peritoneum, we united with a single stitch the fundus or the anterior wall of the corpus uteri to some point in the peritoneum near the pubes. In a few weeks examination usually disclosed the uterus again retroverted and thereby demonstrated the inadequacy of this technic; then several sutures were used instead of one with the same result; then before suturing we scraped off with a sharp knife the peritoneal surface so as to give raw surfaces to be united and the result was strong broad cicatricial union and permanent fixation; in fact, immobilization of the uterus; then was written *the tragic and humiliating chapter of mechanical fixation* of the uterus, a chapter which told of obstruction of the bowel, dystocia, rupture of the parturient uterus and other obstetric calamities not to mention a formidable list of disabling, distressing consequences, neurotic and circulatory, local and general. Ventral fixation then relegated to the dark ages of surgery soon gave way to ventral suspension of the uterus by less barbarous methods—an operation popularized by Howard Kelly which in the final and successful evolution resulted quite uniformly in stable equilibrium of the uterus, and at the same time left it free in its normal range of movements. The principle was simple and effective; it was to unite to the anterior parietal peritoneum, not the fundus or the anterior wall of the corpus uteri but the posterior wall, and, what is most essential, to that part of the posterior wall just back of the fundus, a surface about one-half inch back of a line connecting the uterine ends of the Fallopian tubes. This surface was united to parietal peritoneum near the uterovesical reflexion. Stable equilibrium and permanent uniform results were secured by the simple change in the selection of surfaces to be united without denudation of the united surfaces and with two or three absorbable catgut sutures; that is, very light adhesions of these surfaces were sufficient. Moreover, this union, by lifting the posterior wall of the corpus against the parietal peritoneum, also served to tilt back the cervix so as to place it nearer to the hollow of the sacrum—a most essential mechanical factor in the correction of retroversion, for if the cervix be normally near the sacrum, the corpus does not have space in which to retrovert.

This operation, modified by myself in a personal experience of several hundred cases, was in a degree satisfactory both as a means of correcting the displacement and in its freedom from the distressing mechanical results which had discredited the obsolete operation of fixation It, however, may give rise to obstruction of the bowel, for it always left a more or less constricted passage around the uterus, especially if the adhesions pull out into cicatricial bands under which intestine could work its way and be compressed. Such accidents, with grave results, have been reported from time to time. Moreover, the operation in incompetent hands, although intended to produce light adhesions only, sometimes sets up union so strong and cicatricial as to amount to the much-dreaded fixation already condemned. These things being so, I finally disregarded my own satisfactory results and those of others, and have almost abandoned the operation, and in place of it for several years have substituted one after another of the various ligament-shortening operations.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

In taking leave of the suspension operation, which in the evolution of the subject has held so large a place, I pay it my very appreciative respects; it was a tried and trusted friend; it hardly ever failed; it never, in my personal experience, was followed by bad results which I could attribute to it: unfortunately, however, it is beset by the sentimental objection that it is not anatomic, and, under indictment therefore by the surgical purist is charged with the crime of being unsurgical. It may plead, however, extenuating circumstances, inasmuch as it has suffered from the evil relations and evil associations of fixation, the sins of which, by confusion of the two operations, have been visited on it most unjustly. And so, not without a sense of disloyalty, I dismiss, temporarily at least, an old benefactor, and pass to the more approved ligament-shortening operations.

There is, perhaps, more scientific indication for shortening the uterosacral than for shortening the round ligaments because these ligaments should maintain the normal short distance between the cervix uteri and the hollow of the sacrum, and because shortening them therefore may fulfill an essential indication, but with due respect for contrary opinions no uterosacral operation, so far as I am aware, has been developed to the degree of satisfactory stable results; that is, the shortened uterosacral ligaments do not hold well. They are liable to pull out again soon after the shortening, causing the operation to fail.

The recent operation of Harris,[1] by which a new ligament is formed to supplant the uterosacrals by utilizing the long tendon of the psoas parvus muscle, is too new to permit an estimate of its value; it probably is destined, however, to go the winding way of artificial ligament operations.

Shortening of the broad ligaments is not germane to this discussion, except as it enters incidentally into the round ligament operations.

Perhaps we may drop the curtain on Alexander's operation now regarded as obsolete. The substitute operation once advocated by Goldspohn, while reasonably effective, I would discard as requiring an unnecessary amount of surgery for the accomplishment of the purpose, especially since this surgery might, in the hands of an unlucky surgeon, weaken the region of both inguinal canals and the abdominal rings and thus give rise to hernia, to say nothing of its increased danger of sepsis. The various operations of doubling the round ligaments on themselves or of suturing them in front of the uterus, although very useful in their time, now, in the face of more recent procedures, appear to be passing into disuse. They always were open to objection of frequent inadequacy for permanent results.

Perhaps without fear of much contradiction we may eliminate from serious discussion all ligament-shortening operations except those which belong to the most recent era, an era which began with the operation of Gilliam. This operation has been modified in technic by Barrett, myself, and others, and has been somewhat, though perhaps not very materially improved. In addition to the merit of being anatomic, and therefore surgical, it gives reasonably permanent results, although possibly not so permanent as the suspension operations of Kelly, already described, approved, and reluctantly laid aside. Gilliam, so far as I am aware, took the longest step toward placing the surgical treatment of retrodisplacements on a scientific basis. Just what form of this method of supporting the uterus by drawing the round ligaments through other structures and fastening them there will stand the final test of experience against all others, the future must decide. The operation is not quite adequate, however, inasmuch as it fails like all others of its kind to hold the cervix back in its normal location near the hollow of the sacrum, an essential requirement for perfection still unfilled by any method so far proposed.

A radical departure from the Gilliam technic, although not entirely different in principle, inasmuch as it passes the round ligament through other structures, is the operation of drawing the round ligaments through the broad ligaments and fastening them on the posterior wall of the corpus uteri. Clarence Webster, I think, first described this operation, and therefore is entitled to the credit of literary priority. I believe it was earlier performed by Frank Andrews. It has been successfully championed by Baldy. I have performed it more frequently than any other for several years, and so far as I have been able to observe results, am inclined to give it a great deal of preference. This and other round-ligament operations are thought to be inadequate and therefore contraindicated when the ligaments are so attenuated as to be incapable of giving much support and in such cases many revert to the suspension operation by adhesion.

I think I would favor this operation even with an attenuated ligament inasmuch as it carries along with the ligaments considerable peritoneum, which becomes adherent and gives supporting power. In fact, the peritoneal element in posterior attachment is a most significant factor—almost as significant as it is in ventral suspension; it combines the advantages of ligament shortening with seroserous adhesions and is free from danger of resultant obstruction of the bowel so much feared in the ventral suspension and the original Gilliam operation.

The pessary, recognized in former times as being of great value, has fallen into unmerited disuse and the correct application of it has become almost a lost art.

One additional word: In this age of dramatic surgical achievement in the abdomen, let us remember that our fathers of the last generation developed plastic surgery on the vaginal side of the pelvic floor to a surpassing degree. Let us keep in sight the fact that any abdominal operation for retroversion or descent, however well selected or performed, may be of little avail against the counter-influence of a relaxed pelvic outlet, and that good plastic work below therefore may be indispensable. Perhaps it is true that the pioneers did better plastic work that we are doing now. It would be interesting entirely if under the blinding influence of major surgery, plastic gynecology should become a lost art.

THE DISCHARGE OF LUNATICS BY HABEAS CORPUS PROCEEDINGS*

FREDERICK A. FENNING, LL.M.
Of the Bar of the District of Columbia
WASHINGTON, D. C.

The constitution of the United States[1] provides that "the privilege of the writ of habeas corpus shall not be suspended unless when in cases of rebellion or invasion the public safety may require it."

It is important at the outset that we have clearly before us in the consideration of this paper a precise idea of the legal significance and aim of the great writ to which it relates. A concise definition, which has generally been accepted as a most complete one, is that given in "Hurd on Habeas Corpus:"[2]

> The writ of habeas corpus is that legal process which is employed for the summary vindication of the right of personal liberty when illegally restrained.

It is along the line of this definition that I proceed to a discussion of the application of the writ respecting a single class of individuals, namely, the insane. Reverting to the historical, it may be of importance to recall that the original necessity for the writ of habeas corpus arose from a great many conditions which demanded remedy, one of the least of which was lunacy confinements. One of these conditions, as will be remembered, and a most important one, was the practice of imprisoning for debt. By far the large majority of habeas corpus cases in the old reports, both English and American, relate to restraint of liberty for reasons other than alleged or adjudged lunacy. We find, at the present day, however, that this writ, designed more particularly for divers other necessities, is being used to an astounding extent in lunacy cases. The increase in its use within the memory of living men has been so marked that it may well be inquired whether it has not become an abuse of privilege. The increase of the popularity of habeas corpus proceedings in lunacy cases has been due to several causes, to some of which I think it highly important that we give thoughtful attention. It is only by a full appreciation of the causes, taken with an intelligent comprehension of the effects that we can proceed properly and with well-founded hope toward a reform.

Let me emphasize that it is not the purpose of this paper to argue for one moment for a suppression of the writ as such. The writ of habeas corpus came into use by reason of a recognized necessity for such a process, and it has undoubtedly become an invaluable part of our judicial system. It is my desire to point out, if I may, the abuse of privilege in the obtaining of this writ by lunatics and those acting in behalf of such persons. In so far as applies to the issuance of the writ in cases of lunatics, I argue for a limitation of such use. In using the word "lunatic" I am not unmindful of the efforts of some of the medical profession to abandon the word, to substitute for it some word or phrase less harsh, something which signifies illness. This position taken by medical men is based, of course, on the modern view of insanity, and is at once both in keeping with that enlightened view and of kindly intent to the patient and his family. With these efforts I am in full sympathy, but as this paper treats the legal side of the subject, I use the term "lunatic," a word which the statutes and the decisions have given a distinct place in medical jurisprudence.

In the first place, in the case of every applicant there must have been an actual incarceration, either as a preliminary act under general police or public health regulations, or by decree of a court in confirming a due inquisition. Few persons apply for a writ of habeas corpus during the period of temporary detention. The applicants for the writ are in practically every instance, those who have been adjudged insane. Time was, we all remember, when persons supposed to be insane were taken to the nearest jail or prison and there confined without examination, without hearing, and without day, and it was the suffering of those thus confined that brought about through Pinel and others the recognition of the great fact that there is nothing of the criminal about an insane person, but that he is simply a sick man. This truth has come to have so firm a place in the mind of society that no longer is it possible—nor indeed is it the desire—to incarcerate an alleged lunatic without a full and fair hearing. It means a great deal, therefore, when we realize that the lunatics applying for discharge by habeas corpus are, as I said before, in nearly every case adjudged lunatics. They are not suspected individuals who have been summarily confined, but are those who have had their day in court, and have been found, in orderly manner by competent tribunals, to be in need of treatment for mental disease. As to these hearings in the several jurisdictions, it may be said that they have at least one feature in common, namely the fairness with which they are conducted toward the alleged lunatic. An examination of the widely differing proceedings throughout our country must convince one that in every instance the man whose sanity is in question has a fair opportunity in the presentation of his case. The variance in these hearings extends all the way from the admirable practice under the New York and Massachusetts laws which treat the patient as a sick man, to that in the District of Columbia which requires his examination before a jury of twelve laymen. A great deal has been spoken and written and much more can be said about the system which gives a jury of laymen the right to determine whether there should be commitment for mental disease. If all hospitals were private institutions conducted for gain, and the superintendents thereof were under lax regulations and without inspection laws, there might be some reason for placing twelve laymen between liberty and confinement. My own opinion, based on a study of European laws and those of some of our own states, and a practice specializing in such matters, is that the commitment may be safely entrusted to a judge. Be the hearing conducted in whatsoever manner, it must be conceded that the practice of committing sane persons to insane hospitals is a relic of ancient days or a creation of vivid imagination. Such being the case, the burden shifts, after adjudication, and it is, or certainly it ought to be, incumbent on the adjudged lunatic to show that he is sane if he is to secure discharge by habeas corpus. This burden should extend further. It should require, as suggested by a committee of the New York State Bar Association, a showing of *prima facie* sanity before the issuance of the writ of habeas corpus. The report of the special committee on the commitment and discharge of the criminal insane, presented at the meeting of that association held in Rochester in January, 1910, recommended that a person confined in any state hospital for the insane might make application for a writ of habeas corpus only on a written verified petition accompanied by a certificate made under oath by two qualified medical examiners in lunacy. It further recommended that the examiners in lunacy be required to give the reasons on which they based their belief as to the sanity of the applicant. A requirement such as this would do much to reduce the number of hearings on writs of habeas corpus, for it would operate to prevent the issuance of a large number of such writs.

[1] Constitution, Art. 1, Sec. 9, par. 2.

[2] Hurd on Habeas Corpus, p. 143

Certain "leeches" of the legal profession exist in every community, and there is a form of this species which fastens itself on hospital patients. Through the efforts of these shysters, patients who would not otherwise think of such a thing, and who really do not desire freedom, are led to apply for discharge on writs of habeas corpus. Petitions in such cases are not infrequently signed by the attorney as next friend of the patient. The next step, often followed, is to file the proceeding *in forma pauperis*. Thus the attorney after one short conversation or after receiving a letter or a postal card from the patient, is enabled without further consultation or a medical examination, and without taking up the matter with the hospital physicians, to indulge in what may be properly called a "fishing expedition." On the hearing if the patient is remanded, the attorney has lost simply the questionable value of his time, but if the patient is discharged the attorney demands substantial compensation. In a recent case which came under my observation the discharged patient had $600 accumulated savings, of which he complained that the attorney took $135 as a fee and borrowed $300. It is important to add that the remainder supported the patient two months and he was then recommitted to the hospital from which he had been discharged! As to his mental condition, it must be said that while at the time of his discharge he was quiet and contented, the strenuous life which he led during his two months' freedom, with attendant excesses and indulgences, changed him greatly and he returned with his mental disorder aggravated to an alarming degree. This practice, encouraged and fostered by the unrestricted issuance of writs of habeas corpus, has grown in some jurisdictions until it is nothing less than a cruel wrong on the patients and an outrage on justice. One remedy lies, as above suggested, in a requirement that the patient submit with his petition *prima facie* evidence of his sanity, or, in other words, that before burdening the court and hospital authorities, he obtain a substantial showing of reputable medical evidence as a basis for his petition.

Another class of patients seeking freedom through the great writ are the paranoiacs. As is commonly known, paranoia is a most dangerous type of mental disorder. The paranoiac invariably possesses cunning, usually in a marked degree. These patients differ from those to whom I have referred as being preyed on by unscrupulous attorneys, in that the personal activity of the patient is conspicuous in his efforts to obtain discharge. At Dannemora (the New York Hospital for Criminal Insane) the superintendent recently reported that the majority of his patients who were seeking writs of habeas corpus were paranoiacs, and that during five years four such patients who had been thus discharged had committed suicide. The records of many courts also show that in such cases the termination of one proceeding by the remanding of the patient simply marks the beginning of a new proceeding. Many patients suffering from this form of mental disorder have obtained six and eight writs; and as long as the writs are procured so easily, they will doubtless continue—to the retardation of the proper business of the courts, the disheartenment of hospital authorities, and the physical and mental detriment of the patients themselves. The court proceedings in such cases are unnecessary, quite as much so as those in the class of cases earlier discussed. It is self-evident that a requirement of medical evidence in support of a petition for a writ of habeas corpus would perforce prevent oft-recurring applications from the same patient.

In a paper prepared in 1909, Dr. Robert B. Lamb, superintendent of the Matteawan State Hospital, reported the subsequent history of forty-one patients for whom during a given period writs of habeas corpus had been obtained. Seven were remanded to the hospital and thirty-four were discharged. Of these thirty-four, fourteen found their way either to prison or asylum, eight were troublesome to their families because of mental disturbances, three were unable to earn their living and were cared for by relatives, six disappeared from view, two committed suicide, and one succeeded in becoming partially self-sustaining.

In the District of Columbia between given dates in 1905 and 1909, fifteen patients secured their discharge from the Government Hospital for the Insane on writs of habeas corpus. By reason of nearly all of these men having been soldiers and sailors and not residents of the District of Columbia it has been impossible to trace the subsequent history in every case. Of the number thus discharged, however, four were later taken in custody and recommitted to the hospital, one committed suicide, one committed a violent assault in a northern city and was placed in another hospital where he is now confined, one was admitted to a New York State hospital for the insane, and one became an inmate of an institution in the West and by his recent correspondence with a prominent government official has given evidence of profound mental disorder.

It is well worthy of note that during this same period 1,256 patients at the Government Hospital for the Insane were discharged by the superintendent without any proceedings whatsoever, and approximately 900 more were similarly released by the superintendent on parole to relatives and friends.

In an early case[3] in this country it was held that:

> "No principle of right is violated in putting a reasonable and salutary restriction on the liberty of a person who, from the loss of reason and judgment, is unable to provide means for his own cure or who is liable to use freedom from restraint in such way as to increase or prolong his malady."

In the light of this very sensible doctrine, it is clear that after a proper adjudication the patient in confinement is not being deprived by illegal restraint of the right of personal liberty—to use the language of Hurd's definition—and should not, therefore, be entitled to a writ of habeas corpus except on a proper advance showing of mental capacity.

As we consider the rights of the patient, so must we not overlook the rights of society. The men, women and children who are daily on the streets and in other public places have distinct rights which are of as much importance and value to them as any rights of the adjudged lunatic. "Man," says Montesquieu, "is born in society and there he remains." The incompetent is a component part of society and it is therefore necessary that certain restrictions be placed on him that he may not do violence to the welfare of the greater number. To be sure, the insane, as wards of the court, are peculiarly entitled to the most jealous protection of the court, but it is equally true that the great body social is entitled to the protection of the institutions of justice in the interests of the general welfare of the race. The welfare of the adjudged lunatic, then, should be considered, not of itself, but coordinately with—I am tempted to say, subordinately to—that of society. On the one hand, the discharge of an adjudged lunatic on evidence lacking clear proof of restoration to reason may for the moment please and satisfy the patient, and. on the other hand, it may harass and endanger his fellow citizens without number. In recent years the Rhode Island Supreme Court has spoken on this point with a fearlessness that is refreshing. In the case of Ex parte Palmer[4] the court after hearing the evidence of nine or ten physicians—several of whom were of wide reputation—to the effect that the petitioner was not insane, and on the other side that of four physicians of known probity and experience that it was dangerous to the community for petitioner to be at large, remanded him with these words:

---

[3] Matter of Josiah Oakes, 8 Law Reg. 122.

> "Charged as we are with the high and imperative duty of protecting the people of the state, as far as lies in our power, from physical injury and violence at the hands of irresponsible persons, we are of the opinion that in order to warrant us in discharging the petitioner from his confinement he must show by a clear and strong preponderance of evidence that he is not insane and that his going at large will not be dangerous to the public peace. That so strict *a rule does not obtain* in all cases of this sort, that is, in petitions under the statutes of the various states, for the release of persons confined in insane asylums, we are well aware. But we think it should be the rule in a case like the one before us, and we therefore adopt it and shall be governed by it."

In this decision the protection of the court was extended to the community, the court declining, as you have noted, to take the responsibility of discharging because of a lack of "a clear and strong preponderance of evidence that he is not insane and that his going at large will not be dangerous to the public peace."

One needed reform, as I have tried to indicate, is the establishment by the petitioner of a *prima facie* case at the filing of the petition. Another is a uniformity of practice which will result in habeas corpus cases being heard before the nearest judge of competent jurisdiction without the questionable aid of a jury. Some time ago attention was directed by the superintendent of one of the New York state hospitals to a growing practice of the courts of granting writs returnable before other justices in distant parts of the state. The necessity for such a proceeding is purely imaginary; the burden that it puts on a disinterested and honorable institution and its officers is at once harsh and absurd. A striking instance of this abuse was that of a patient in the Willard (N. Y.) State Hospital, who, in September, 1909, after having been remanded in three or four habeas corpus proceedings, secured a writ returnable before a justice in Brooklyn nearly four hundred miles distant. A criminal in California[5] who wanted discharge on a writ of habeas corpus tried this plan of going beyond his own jurisdiction but in that case the supreme court of the state laid down a doctrine of common sense which ought to be appreciated by all who read it. The court said:

> "The legislature can never have intended that a party imprisoned under sentence of conviction for a misdemeanor should have the privilege of selecting from the judiciary of the whole state the individual to whom he prefers to make his *application*, however distant from the place of his detention, and compel the officer having him in charge to convey him, at the expense of the county, it may be from San Diego to Klamath, in order that he might avail himself of a remedy which the local judge of his county was equally authorized to grant. Nor need he stop here; the refusal to discharge by one judge is not a bar to another application before a different judge. After failing in his first application, the party may sue out another writ before a different officer, *and thus the term of his imprisonment* may be passed in traveling from one part of the state to another, at the expense of the county in which he was convicted, to the entire subversion of justice."

Hearings on writs of habeas corpus, by reason of the supposed exigencies requiring their issue, should be conducted by a judge without a jury. The practice has grown, however, of courts referring the issues raised in such hearings to a jury. This is not because a hearing by the court would amount to a violation of the right of jury trial, for the right of jury trial in habeas corpus cases has never existed. Going back to Blackstone's Commentaries we find the learned author commenting on the fact that the right of trial by jury was not recognized as existing in favor of an alleged lunatic under the common law.[6]

An alleged lunatic cannot be committed it is true, and cannot be tried to determine his mental condition, except by "due process of law," but as Judge Cooley points out in his work on "Constitutional Limitations,"[7] "The term 'due process of law' is by no means confined to trial by jury, but the term covers a variety of judicial proceedings."

There ought to be no room for doubt as to the proper legal method of conducting such inquiries. In the first place, the federal law provides[8] that in habeas corpus cases "the court, or justice, or judge shall proceed in a summary way to determine the facts of the case, by hearing the testimony and arguments, and thereupon to dispose of the party as law and justice require."

You will note that the court is required to proceed summarily, and Bouvier[9] defines a *summary proceeding* to be "a form of trial in which the ancient established course of legal proceedings is disregarded, especially in the matter of trial by jury."

Still another recognized authority on the subject, Professor Church, in his work on "Habeas Corpus,"[10] confirms this doctrine, using this language:

> "There is no provision in the Constitution of the United States, neither is there in any state constitution, which gives the right to have these issues of fact tried by a jury in such proceedings. The constitutions, federal and state, provide substantially, that the right of jury trial shall not be violated, but it is no violation of this inestimable privilege to deny it in chancery *proceedings, preliminary examinations* and proceedings by habeas corpus."

This matter becomes one of great moment when we observe, as has sometimes been alleged, the judge taking an open and positive position as to the *mental condition* of the patient while the jury takes an opposite view and the court confirms the jury's verdict. The judge in such cases, by reason of his ability to weigh evidence and his unbiased attitude, can render a verdict just to both the patient and the state, while a jury of laymen, torn by conflicting emotions and personal equations may, and frequently will, decide a mental question on any ground except that of the evidence.

It is the abuse of privilege which leads to corrective measures. A reform must come when an abuse becomes too flagrant. In these cases, we are coming, very generally, to a recognition that the petitioners are getting not only what a humane law and practice afford them, but certain so-called privileges not warranted by the intent of the law and of infinite harm to public institutions, to judicial procedure and to the patients themselves. The time is ripe, therefore, for an enforcement of the rights of the community at large, and if we concur in this view we are brought face to face with the question of how the existing abuses are to be corrected. I have endeavored to outline some needed changes in our laws as well as in our practice under existing laws. There remains to be brought to attention at least one other important method of correcting the evil. I refer to a dissemination of knowledge among the people at large as to present-day methods and management of public institutions for the care of the insane. A growing movement in such hospitals of giving publicity and of inviting medical cooperation is doing much to bring closer sympathy between physicians in charge and those in private practice. For two years past the government hospital at Washington has conducted each winter a series of staff meetings to which the physicians of the city have been urgently invited, and which invitation, it is gratifying to know, has been accepted by a large number of active practitioners. At these meetings, methods used in the examination, the care, the amusement, and the varied treatment of the insane, are discussed fully and freely. By such means the hospital physicians are getting the confidence of the people at large through the family physicians, and the old horror of hospitals—born and nurtured in ignorance—is being replaced by an intelligent idea of the work which the hospitals are striving to perform. This labor of the institutions—I speak with particular reference to the large government and state hospitals—is full of discouraging aspects. The trials incident to the work are materially reduced by cooperation and appreciation such as I have just mentioned, but a further step will be attained when in addition is added the confidence of the legislators, the bench, the bar and the jury box. It may be a far cry to the time when such universal confidence will exist. It ought not to be, for the cause is that of the people. The people have rights which the legislators ought to respect and will respect when they are insistently and persistently presented. As for the bench, the bar and the jury, I believe that a uniform stand by the courts for the protection of the many will be a guidance to the attorneys, as it must be a rule of action for the jury. In all the literature of the law no safer, saner or more fearless decision stands out than that of Judge Ludlow of Philadelphia.[11] This distinguished jurist, reviewing the evidence in a habeas corpus case, and remanding the patient to the hospital, said:

> "To take a proper and just responsibility in such a case as this, requires not bravery but courage—not that quality which sometimes degenerates into temerity, and is reckless of danger, but rather that other quality which is the result of reflection and is always cool and collected. Where our path of duty is plain we ought judicially to be courageous, not brave."

It was nearly forty years ago that Judge Ludlow uttered these words. He was the precursor of other jurists, who have maintained in positive terms their determination to protect society from those who would do it violence, as well as to protect those who would do violence to society. The goal which we seek is the better protection of society, without the releasing of any of the proper privileges and safeguards extended by the law to the mentally deficient. The difficulties in our way are numerous. Although the path of progress at times seems clear, there are ever present obstacles. Some of these are founded on honest bases and must be overcome by a campaign of education; others have their support neither in the law nor in righteousness and must be dealt with vigorously. Until medical science can cure all mental ills, those who suffer from such affliction must be cared for and directed, in ways that are pleasant, if you please, but always in paths that do not permit these unfortunates to be of danger to themselves or to their fellows. The great agencies of the law must be wide open to them, but with the limitations that are essential for the proper administration of justice, and the safety of all the people.

SALVARSAN AND SODIUM CACODYLATE *

HENRY J. NICHOLS, M.D.
Captain, Medical Corps, U. S. Army
WASHINGTON, D. C.

The object of this paper is to present the results obtained by applying to sodium cacodylate the experiments which demonstrated the wonderful destructive action of salvarsan on the spirochetes of syphilis. These experiments are laid down in Ehrlich and Hata's recently issued monograph,[1] and, in brief, they consist, first, of the determination of the tolerated dose of a given substance for normal rabbits, and, second, of the determination of the curative dose for rabbits infected with *Spirochæta pallida.* The results are expressed in the form of a ratio, C: T. Hata has shown that the ratio for salvarsan is at least 1 to 10 with a single intravenous injection.

Interest among clinicians of this country in sodium cacodylate in the treatment of syphilis seems to date from an article by Murphy,[2] who gave a summary of the status of salvarsan at that time and then said:

> It has been announced that this drug will not be given to the profession for a number of months, a fact which forced us to try other preparations of arsenic. The one with which I have been most familiar is the sodium cacodylate, which we have been using for seven years to allay the pain of metastatic, osseous carcinomata.

He mentioned three cases in which the drug, given intramuscularly, seemed to have had a high spirillicidal power. Murphy's lead has been followed by a number of clinicians, and while few published reports have as yet appeared, it has become evident that the results are not uniform. Sodium cacodylate is, of course, not related to salvarsan in any way, except that it contains arsenic, and it would be very surprising if one could substitute, off-hand, a stock preparation for a highly refined product like salvarsan. Still, in view of our ignorance of the actual spirillicidal power of sodium cacodylate, and of the great interest in the general subject, it seemed worth while to fall back on the experimental method.

---

TOLERATED DOSE

The problem, then, is to work out the ratio C:T for sodium cacodylate. Runnels[3] has recently given a review of the chemistry and physiology of the cacodylates and has emphasized the subject of purity of the drug. He examined the best of two samples bought in the market and found a sodium cacodylate content of 77.59 per cent. and concluded that the remainder consisted almost solely of water. The preparation used in the following experiments was Merck's, which came in brown glass bottles of one-eighth ounce capacity. Tested by the method of Imbert and Astruc it gave a cacodylate content of 67 per cent. There was no evidence of other impurity than the water of crystallization.

The tolerated dose was worked out for intravenous administration, as this is the most definite method in which to determine curative action. The drug was dissolved in salt solution in proportions which allowed the desired amount to be given within 5 c.c. Table 1 shows the results of injection of various quantities.

TABLE 1.—THE EFFECT OF VARIOUS DOSES OF SODIUM CACODYLATE ON RABBITS OF DIFFERENT WEIGHTS

Rabbit	Weight gm.	Dose per Kilogram	Result
1	2150	0.025	No visible effect.
2	2015	0.01	No visible effect.
3	2055	0.01	No visible effect.
4	2180	0.15	No visible effect.
5	1955	0.15	In a short time drowsy, with some paresis of hind legs.
6	2150	0.2	Drowsy; paresis of hind legs; rapid respiration; very sick.
7	2170	0.2	Drowsy; paresis of hind legs; rapid respiration; dead in twelve hours.
8	2020	0.25	Same symptoms; dead in twenty hours.
9	1970	0.3	Slight symptoms; recovered.
10	2000	0.3	Same symptoms; dead in twenty hours.

All the animals affected showed the same symptoms of stupor, rapid respiration and paresis of the hind legs. The animals that died showed congestion of the lungs and a small exudate in the pleural cavities.

The tolerated dose is the largest that can be given with safety to life; in other words, it is just short of the minimal fatal dose. In the present instance, "T" may be taken as 0.2 gm. per kg. for intravenous administration. Runnels considered 0.3 gm. per kg. as a maximum safe dose in rabbits, but this was by the subcutaneous method of injection, and with half grown animals.

CURATIVE DOSE

The curative dose was worked out on chancres of the scrotum and on lesions of the testicle produced by the eighth, ninth and tenth generations in rabbits of spirochetes from a case of human syphilis.[4] A complete protocol of one of the rabbits is given below.

RABBIT 2 (XX).—Oct. 4, 1910: Black; right testicle injected with 1.5 c.c. of a citrate mixture of serum from the testicle of Rabbit XVII; eighth generation; spirochetes abundant. October 24, small indurated patch in scrotum. October 31, testicle enlarged; nodule in epididymis; oval chancre in scrotum; spirochetes abundant in testicle by dark-field examination, twenty-seven days after inoculation. November 2, serum positive by Wassermann test. November 7, skin lesion much larger. November 9, serum positive. November 17, spirochetes present in testicle. November 21, large chancre, 24 by 12 mm. November 25, spirochetes present in chancre; same size; weight 1333

TABLE 2.—SUMMARY OF THE FINDINGS IN RABBITS AFTER THE INJECTION OF VARIOUS DOSES OF SODIUM CACODYLATE

Rabbit	Weight gm.	Condition at Time of Treatment *	Dose per kg.	Examination for Spirochetes After Treatment 1st Day	2d Day	3d Day	4th Day	5th Day	6th Day	7th Day	8th Day	9th Day	10th Day	11th Day	12th Day	Remarks
1 (XIX)	2330	Large chancre of scrotum, 18x18 m.m. Sp.+	.005	+.005	:	+	:	+	+	:	:	+	+	:	:	No effect on spirochetes or on lesions.
2 (XX)	1333	Large chancre of scrotum, 24x12 mm. Sp.+	.005	+.005	:	+	:	+	+	:	.01 pro kg. 606	—	—	—	—	No change in spirochetes or in lesion until 606 was given; then rapid healing.
3 (XXXII)	1900	Lesion of testicle size of olive...... Sp.+	.025	+	+	+	+	:	:	+	+	:	:	.01 pro kg. 606	—	Lesion became smaller; spirochetes persisted, active and numerous until 606 was given.
4 (XXXV)	1960	Lesion of testicle size of large olive.. Sp.+	.025	+ ±	+	±	:	:	:	:	+	+	:	:	:	Lesion became smaller; spirochetes partly immobilized at first.
5 (XXXIV)	1930	Chancre of scrotum, 12x16 mm...... Sp.+	.05	+	+	+	+	+	:	+	:	:	:	:	:	No effect on spirochetes or on lesion.
6 (XXXIII)	2090	Large diffuse lesion of testicle....... Sp.+	.075	+	+	:	+	+	+	+	+	:	:	:	:	No effect on spirochetes or on lesion.
7 (XXIX)	2240	Lesion of testicle size of olive....... Sp.+	0.1	+	+	+	+	:	+	:	:	:	:	:	:	No effect on spirochetes or on lesion.
8 (XXXVI)	1975	Chancre of scrotum, 18x17 mm...... Sp.+	0.15 "606"	+	+	:	+	+	:	:	:	:	:	:	:	No effect on spirochetes or on lesion.
Hata XI	2360	Two chancres of scrotum, 20x26 mm. Sp.+	0.015	—	—	—	:	:	:	:	:	:	:	:	:	Spirochetes destroyed in twenty-four hours; lesions healed in two and three weeks.

* + = Present, active; ± = present, motionless; — = not found.

---

[3] Runnels: The Carbon Compounds of Arsenic in the Treatment of Syphilis, New York Med. Jour., xcii, No. 22, p. 1053.

[4] Nichols: Experimental Yaws in the Monkey and Rabbit, Jour. Exper. Med., xii, No. 5, p. 620.

gm.; 0.005 per kg. sodium cacodylate intravenously. November 26, spirochetes present, sluggish in movement; 0.005 per kg. sodium cacodylate intravenously. November 28, spirochetes present, active, numerous, no change in lesion; serum positive. November 30, spirochetes present, active. December 1, lesion 22 by 17 mm.; spirochetes present, active. December 3, 0.01 per kg. salvarsan intravenously. December 4, spirochetes not found. December 5, spirochetes not found; lesion 16 by 16 mm. December 6, spirochetes not found; lesion much smaller. December 9, spirochetes not found; lesion much smaller. December 10, spirochetes not found; lesion nearly healed. December 12, lesion nearly healed; doubtful serum. December 19, no remains of lesion, serum negative.

When in the course of this work the dose of 0.025 per kg. was reached, it was at first thought that some curative effect was becoming evident in Rabbits 3 and 4, because the lesions became smaller after treatment, and the spirochetes were in part immobilized for two days in one animal; but higher doses failed to show anything of the kind, and the testicular lesion is, naturally, subject to certain fluctuations.

As is evident from the results recorded in Table 2, it is impossible to demonstrate any spirillicidal action for sodium cacodylate in infected rabbits short of seriously injuring or killing the animal. Hence "C" cannot be given any value, and the ratio C: T, or 0/0.2, signifies no specific action.

COMMENTS

Of course facts gained from experiments on animals often cannot be directly transferred to human medicine; but much of our knowledge about salvarsan and other experimental substances has been so transferred and no reason is apparent why sodium cacodylate should be an exception. Dawes and Jackson[5] have shown that any therapeutic effect sodium cacodylate may have is due really to decomposition and reduction products such as cacodyl, arsenious and arsenic acids. The amount of reduction depends largely on personal idiosyncrasy, and in this way a very uncertain element is introduced. It is possible that more reduction is effected by several small subcutaneous or intramuscular injections than by a single large intravenous injection, and that the nascent acids may have some favorable action on the tissue reactions to the spirochetes, or even on the spirochetes themselves; but it is fair to conclude that neither sodium cacodylate nor its reduction products have any considerable spirillicidal action. Their organotropic properties are fully as strong as their parasitotropic properties. Many substances which had a ratio of 1 to 2 or less were discarded as useless in the elaboration of salvarsan.

For all practical purposes salvarsan should be regarded as a new substance and not merely as a new arsenical compound. The arsenic is only a part of a complicated instrument and would be of little value alone. The arsenic must be reduced, trivalent and in firm combination with the benzol ring; and the benzol ring must be substituted with the OH group and the NH_2 group in the *ortho*-position before a maximum destruction of spirochetes is possible. From this point of view, sodium cacodylate has no more relation to salvarsan than a pair of artery forceps has to a lithotrite in the extraction of a stone from the bladder.

RESISTANCE TO TREATMENT

When sodium cacodylate was first used, it was feared in some quarters that the spirochetes might become resistant to arsenic and fail to respond to a later treatment with salvarsan. So far this has not materialized, and, from the absence of effect on the spirochetes shown in the preceding experiments, it is not likely to be realized. The spirochetes in lesions of several rabbits which had been treated with sodium cacodylate have promptly disappeared after a subsequent treatment with salvarsan in ordinary doses of 0.01 gm. per kg. In the following case, the spirochetes also behaved similarly.

The case was under the care of Dr. M. D'Arcy Magee of Washington, who kindly furnished the following data:

A man, aged 22, date of whose infection was uncertain, had primary lesion and secondary eruption in July, 1910; was given inunctions of mercury and potassium iodid for two months. The patient was seen by Dr. Magee Sept. 27, 1910; there were numerous mucous patches in mouth, scaling syphilids of palms and soles of feet and general glandular enlargement. Sodium cacodylate was given by intramuscular injection up to 18 grains, extending over about a month. The doses were of ½ grain daily at first and then, after a short intermission 1 grain daily. Toward the end of the treatment the patient's breath had a strong odor of garlic. The lesions of the palms and soles improved considerably but the patches remained unchanged. I saw the patient Nov. 14, 1910; spirochetes were found in the mucous patches of the mouth by the dark-ground microscope; serum taken on this day was positive by the Wassermann reaction. November 16, 0.5 gm. salvarsan was given by injection of the alkaline solution in each buttock. November 23, mucous patches healed. November 29, serum weak; hands and feet clean. December 5, gain of 5 pounds since November 30. December 14, serum weak. December 19, serum negative, thirty-three days after injection. The patient has gone to work for first time in four months.

Hence, while there is no indication for the use of sodium cacodylate in syphilis on experimental grounds, it apparently does not interfere with a subsequent treatment with salvarsan.

CONCLUSION

As is noted above, Hata found that the ratio C:T for rabbits was 1:10 for intravenous administration of a single dose. It is probable that for human medicine the ratio is somewhat greater, because in the rabbit the disease is confined to the testicles or scrotum and the spirochetal content of the body cannot be as great as it is in a generalized infection in man. Now we know that, other things being equal, the curative dose varies with the number of spirochetes present; but as destruction is definite at 1 to 10 or in some cases even at 1 to 20, there is good reason to believe, both on experimental and clinical grounds, that a ratio of 1 to 5, or 1 to 2, will suffice to kill all spirochetes in the human body. In some early cases of syphilis patients have beyond reasonable doubt been cured by doses of from 0.3 to 0.6 gm. and 1.2 gm. has been given without ill effects.

At the present time it may be taken for granted that salvarsan is a specific against syphilis and the important question now is: What is the best dose and best method of administration for a given stage of the disease? There is considerable evidence to show that the size of the dose should vary inversely with the duration of the disease. The original Alt method of injecting the alkaline solution intramuscularly seems to hold its own for certainty in results. The Wechselmann method, or the subcutaneous injection of the neutral suspension, has lost much of its vogue on account of slow absorption and liability to necrosis of the tissues. One or more intravenous injections, in some cases, seems to be too brief in action; but observations extending over months are needed on all these points. In Ehrlich's words, "The indications at the present time are not to scatter our strength in trying out new substances but to concentrate all our efforts on improving the method of administration, on strictest asepsis, on carefully increasing the dose, on repeating the treatment and finding suitable adjuvants, in order constantly to approach more nearly to the ideal of *therapia magna sterilisans*."

---

[5] Dawes and Jackson: Physiologic Action, Elimination and Therapeutic Application of Sodium Cacodylate, Used Hypodermatically, The Journal A. M. A., June 22, 1907, p. 2090.

SUMMARY

1. Sodium cacodylate has no spirillicidal action in rabbits infected with *Spirochæta pallida* when tested by Ehrlich and Hata's technic.
2. Treatment with sodium cacodylate does not interfere with a subsequent treatment with salvarsan.
3. The most important question in the treatment of syphilis to-day is, "What is the most suitable dose and what is the most efficient method of administration of salvarsan in a given stage of the disease?

TRANSMISSION EXPERIMENTS WITH THE VIRUS OF POLIOMYELITIS

FINDING THE VIRUS IN THE NASOPHARYNGEAL MUCOSA OF MONKEYS RECOVERED FROM THE ACUTE STAGE *

ROBERT B. OSGOOD, M.D.

AND

WILLIAM P. LUCAS, M.D.

BOSTON

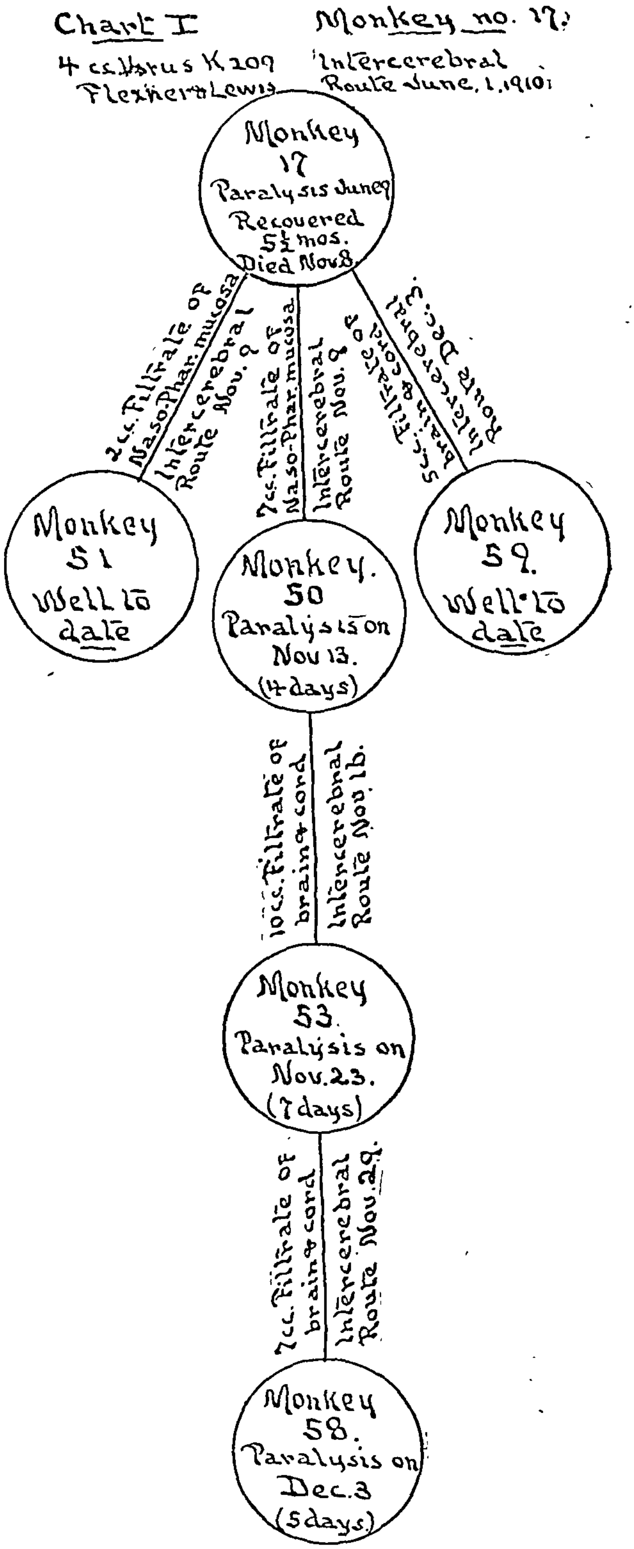
The findings which are recorded in the following protocols and charts came out in an investigation for which we received our original material (virus) from Dr. Flexner and Dr. Lewis, whose encouragement and advice have made this work possible. This investigation is being carried on for the purpose of determining some means of early diagnosis and of the treatment for this condition both in the way of prophylaxis and also during the acute stage. If successful in keeping the subjects alive, we hoped that some light might be thrown on the late treatment of the paralyzed muscles. In a more complete report which is shortly to follow, these questions will be more fully discussed.

In the attempt at keeping the paralyzed monkeys alive success was only partially obtained. For this partial success we are largely indebted to our laboratory assistant, Mr. J. S. Winslow. We have been able to keep four monkeys alive ranging from six weeks to five and a half months. In these cases we feel sure that death was not due directly to the paralysis, but was in most cases due to intercurrent affections and especially to inanition.

The important results deal with Monkey 17 and the series inoculated from the nasopharyngeal mucosa of this monkey, and also with Monkey 54 and the series inoculated from the nasal mucosa of this monkey, and finally with Monkey 6 and its series.

PROTOCOLS OF EXPERIMENTS

MONKEY 17.—This monkey received 4 c.c. of virus K (Flexner and Lewis) on June 1, 1910. The first symptoms of paralysis appeared on June 9; complete paralysis by June 11. The paralysis had begun to improve on July 15, when there was marked improvement in both fore and hind limbs. This monkey lived throughout the summer and had recovered to such an extent that he could feed himself with considerable ease. He could almost turn himself, but could not stand or walk. Early in November his appetite failed, and he died on November 8. Complete necropsy by the Department of Neuropathology showed no intercurrent disease. The nasopharyngeal mucous membrane was removed under careful precautions; was ground up in sterile salt solution and passed through a Berkefeld filter, the resulting amount being 10 c.c. of filtrate. Nine c.c. of this filtrate from the nasopharyngeal mucous membrane were passed by the intercerebral route into two monkeys.



MONKEY 50.—This animal received 7 c.c. of nasopharyngeal membrane filtrate of Monkey 17, Nov. 9, 1910. The first symptoms appeared on November 13 (four days). There was no

paralysis noted. The monkey, however, showed the characteristic nervous prodromal symptoms. He died during the night and necropsy performed early November 14 by the Department of Neuropathology showed typical selective lesions of myelitis.

---

* From the Department of Surgical Research, Harvard Medical School. Work done under a grant from the Proctor Fund.

Monkey 51.—This monkey received, intercerebral route, 2 c.c. of filtrate of nasal mucosa of Monkey 17. This monkey has at no time shown any symptoms, and at the time of writing this report, Jan. 13, *1911*, is perfectly well.

Monkey 53.—On November 16 Monkey 53 received, intercerebral route, 6 c.c. of a salt solution emulsion of the cord and brain of Monkey 50. On November 22, the first prodromal symptoms were noted; November 23, typical complete paralysis. November 23, the animal was killed by etherization. Necropsy by the Department of Neuropathology showed typical selective lesions of myelitis.

Monkey 65.
Paralysis in 48 hours
Killed by Ether
Jan 10.

Monkey 58.—November 29 this monkey was given 6 c.c. of emulsion from cord of Monkey 53, intercerebral route. On December 3 he showed the first signs of paralysis. Paralysis was complete late in the afternoon and he was killed by etherization on the same day. Necropsy by the Department of Neuropathology showed typical selective lesions of myelitis.

Monkey 59.—December 3, 5 c.c. of the filtrate of the cord of Monkey 17, which had been preserved in equal parts of glycerin and salt solution was given by the intercerebral route. There have been no symptoms from this monkey at any time.

Monkey 54.—This was a small baboon which had been sent to us from Springfield, Mass., for the purpose of studying what was supposedly a spontaneous paralysis which had occurred in 1908. This baboon showed marked weakness of her hind legs; she could not jump, but could climb in a fairly active, though clumsy way. She was given an intercerebral injection on November 8 of 2 c.c. of a 5 per cent. emulsion in salt solution which we had obtained from Dr. Flexner on November 5. The first signs of paralysis appeared on November 19. The monkey was kept alive until December 31, when on account of inanition she was etherized and her nasopharyngeal mucous membrane removed under careful precautions, ground up and passed through a Berkefeld filter. This monkey at autopsy showed a well-marked softening of the gray matter, especially of the anterior horns of the cord.

Monkey 62.—This monkey was given 10 c.c. of the filtrate from the nasopharyngeal mucous membrane of Monkey 54 on the morning of January 2. January 3, in the afternoon, Monkey 62 first showed the prodromal restlessness and was apparently very sensitive and was having slight tetanic movements. *There was no paralysis at this time* and he could move about his cage. January 4, in the morning, he was found unable to get up. Paralysis, however, was not present so far as we could make out, though both fore and hind legs were held tonically contracted. During the morning the monkey had respiratory failure and died rather suddenly. Necropsy by the Department of Neuropathology showed in the brain hemorrhages in the meshes of the pia with a moderate number of polynuclear leukocytes and a mononuclear cell infiltration in the medulla. The meninges at focal points showed intense infiltration with various cells, polynuclear, mononuclear, endothelial cells, etc. In the substance of the medulla the glia cells showed a slight reaction to acute ganglion cell changes. There were a few scattered hemorrhages. The cerebrospinal fluid taken at the time of autopsy showed a large number of polynuclear leukocytes, compound granular cells, lymphocytes, etc. The nasopharyngeal mucous membranes were removed under careful precautions and passed through a Berkefeld filter. The cord and brain were also emulsified and passed through a Berkefeld filter.

Monkey 60.
Well to date

Monkey 64.—On January 7 this monkey received 7 c.c. of the nasopharyngeal mucous membrane of Monkey 62. On January 21 the first symptoms of paralysis appeared. The monkey was found in the morning in a very weakened condition, which rapidly progressed until there was a complete paralysis with slight respiratory movement. The monkey lived for twenty-four hours in this practically moribund condition, and died January 22, when a necropsy was performed by the Department of Neuropathology, which showed in the cord degeneration of the ganglion cells, the glia cells were markedly increased and the small blood-vessels were very prominent.

Monkey 65.—On January 7 this monkey was given 5 c.c. of the filtrate from the cord of Monkey 62. January 9 there was complete paralysis. January 10 the monkey was killed by etherization because of marked respiratory difficulties. Necropsy by the Department of Neuropathology showed acute regressive changes in the ganglion cells and an increase of the glia elements in the gray matter of the cord.

Monkey 6.—This was a monkey of our first lot; he received 3 c.c. of virus MA (Flexner and Lewis) by the intercerebral route on March 9, 1910. On March 22 there was a marked drop in his white count from an average of 26,000 to 14,000, which in the light of other findings might possibly be considered as a prodromal symptom; otherwise there were no symptoms from the inoculation. During April and May this monkey received 25 c.c. of a thick emulsion of cord and brain from positive cases in monkeys. This was for the purpose of creating antibodies. At no time were there any symptoms from these inoculations. This monkey was also allowed to live in the cage where several of the monkeys came down with their acute attacks, and drank out of the same cup during the acute onset with one or more monkeys. He at no time showed any symptoms. He was killed by etherization on December 15 and his nasopharyngeal mucous membrane removed under careful precautions and passed through a Berkefeld filter.

Monkey 60.—December 16 this monkey was given 10 c.c. of filtrate from the nasopharyngeal mucosa of Monkey 6 by the intercerebral route. He was also given 12 c.c. of the same filtrate intraperitoneally. There have been no symptoms up to the present time.

These experiments, therefore, show that it was possible to transmit from monkey to monkey a typical poliomyelitis from the filtrate of the nasopharyngeal mucosa of two monkeys dying without other discoverable infections respectively six weeks and five and a half months after the acute stage of the disease. In one case we have been able to transmit the disease from the nasopharyngeal mucosa of a monkey dying in the acute stage. In these experiments it has been impossible to transmit the disease from monkey to monkey by intercerebral inoculation of the cord and brain of these recovered subjects or from filtrates of the nasopharyngeal mucosa of a monkey in apparent good health, which had received a previous intercerebral inoculation of an active virus with only questionable prodromal symptoms, but which had lived in closest contact with monkeys in the acute stage of the disease.

That the virus of poliomyelitis is contained in the nasopharyngeal mucosa of inoculated monkeys was pointed out by Flexner and Lewis,[1] who regarded this membrane as a possible route of spontaneous infection in man.[2] The virus had previously been demonstrated solely in the mucous membrane of recently inoculated animals. The observations recorded here indicate that the virus of poliomyelitis can persist in a viable and infectious state in the nasopharyngeal mucous membrane in the monkey for several months after the acute period of paralysis has passed, and for a far greater period of time than it survives in the central nervous system.

We have noted no case of transmission from monkey to monkey except by direct inoculation, although closest association with subjects in the acute stage has been maintained both by contact and the use of the same feeding utensils and material.

THE FUNCTIONS OF THE STOMACH IN DIABETES MELLITUS

WITH SPECIAL REFERENCE TO THE DETERMINATION OF PEPSIN*

JOHN J. GILBRIDE, A.M., M.D.
PHILADELPHIA

It has been known for some time that the motility of the stomach is usually increased and that the gastric secretion is frequently diminished in diabetes mellitus. In pancreatic diabetes the ferments or zymogens are, according to those who have studied them, frequently affected; the pancreatic ferment, the muscular ferment, and the glycolytic ferment are deficient, suppressed or not activated, and glucose does not undergo combustion, but is excreted in the urine.

The few cases that form the basis of this paper were studied with the object of investigating the secretion of pepsin in patients with diabetes mellitus.

As diabetes mellitus is not a common disease, and as digestion is usually good in diabetic patients, one does not have occasion to examine the functions of the stomach in many of these patients. Some of these patients, however, complain of stomach distress, and some other patients have stomach disease, although they do not have any subjective symptoms of dyspepsia. One of the patients whose case is here reported had catarrhal gastritis, one catarrhal gastritis and dilatation of the stomach, with retention, and one other patient had marked gastroptosis; only one of these, the last, sought advice for dyspepsia or complained of indigestion. Altogether, twenty-two test breakfasts or full test meals were given to these seven patients. It was learned early that one could not wait forty-five minutes to aspirate the stomach after an Ewald test breakfast, but in order to obtain any stomach contents for examination the aspiration had to be performed in thirty minutes, and in some instances at the end of twenty minutes. This was true in the case of L. W., who had gastroptosis. Three attempts to obtain gastric contents in forty-five, thirty and twenty-five minutes, respectively, failed, and the attempt was successful only on aspirating the stomach in twenty minutes, and then only 10 c.c. of contents were obtained. The patient refused further examination. It was also noted that in some instances the stomach was empty in two or two and a half hours after a full dinner.

In the case of S. B., on one examination after an Ewald test breakfast, very little material was obtained at the end of thirty minutes. On one other occasion, however, a pint of contents was aspirated at the end of three hours after a full dinner. At that time the patient was suffering from an increase in the severity of his symptoms, with a greater amount of glucose output in the urine. In the Ewald test breakfast, ordinary wheat bread was eaten; the full meals were those in which only foods permitted in diabetes mellitus were given.

Pepsin digestion was tested by the Mett method. Pieces of glass tubing 2 mm. in diameter containing the boiled white of egg were placed in the liquid to be tested—stomach contents 1 c.c. to 16 c.c. of one-twentieth normal hydrochloric acid—and this put in the incubator for twenty-four hours, after which the glass tubing containing the egg-white was removed and the digestion of egg read off under the microscope by using a mechanical stage. All of these specimens of gastric contents were controlled by testing at the same time other specimens of gastric contents known to contain pepsin.

---

* From the Laboratory of Clinical Pathology, Philadelphia Polyclinic and College for Graduates in Medicine.

Eighteen tests for pepsin were made on the gastric contents of six patients, as shown below. In one, no pepsin was found; in one, although there was a high hydrochloric acid content, in five different analyses, two showed no pepsin digestion; and of the other three tests the digestion was 0.1 mm. In one patient there was a vigorous pepsin digestion; in two other cases the pepsin was somewhat reduced. While in one patient, A. C., the gastric contents were examined three times after an Ewald test breakfast, and three times after a full dinner pepsin was not found in the first five examinations, but a good pepsin digestion was found on the sixth examination. This was after a full dinner.

A short note of the history of each case is here appended.

CASE 1.—Patient, L. W., female, aged 65; born in Germany. Gastroptosis and diabetes mellitus. Amount of glucose in urine, 3.1 per cent. Ewald test breakfast aspirated at end of different periods showed as follows: At the end of forty-five minutes, no contents obtained; at end of thirty minutes only a few drops obtained on end of tube; at end of twenty-five minutes only a few drops obtained on end of tube; at end of twenty minutes 10 c.c. obtained; total acidity 90; free hydrochloric acid 48; pepsin not determined.

CASE 2.—Patient, A. C., female, aged 45; born in Russia; patient kindly sent to me by Dr. A. A. Eshner.

Glucose in urine, 1.8 per cent.

Nov. 18, 1908: Ewald test breakfast; aspirated in forty-five minutes, nothing obtained.

Nov. 23, 1908: Ewald test breakfast; aspirated in thirty minutes, 20 c.c., total acidity 4; no free hydrochloric acid; no pepsin.

Nov. 30, 1908: Full dinner; aspirated in three hours, nothing; no lactic acid; no Oppler-Boas bacilli found; no pepsin.

Dec. 14, 1908: Full dinner; aspirated in two and one-half hours, 30 c.c., total acidity 10; no free hydrochloric acid; no pepsin.

Dec. 21, 1908: Ewald test breakfast; aspirated in thirty minutes; 4 c.c., total acidity 6; no free hydrochloric acid; no pepsin.

Dec. 28, 1908; full dinner; aspirated in two and one-half hours; 20 c.c.; total acidity 10; no free hydrochloric acid; 2.7 mm. pepsin.

Pepsin absent after five examinations; present on the sixth.

CASE 3.—Patient, H. C., male; aged 39; born in Russia; kindly sent to me by Dr. David Riesman. Glucose in urine, 2.8 to 3.2 per cent.

Feb. 5, 1909: Ewald test breakfast, aspirated in forty-five minutes; 150 c.c.; total acidity 38; free hydrochloric acid 28; 4.2 mm. pepsin; digestion good; considerable mucus present.

Feb. 17, 1909: Full dinner; aspirated at end of three hours; 1 pint; total acidity 44; free hydrochloric acid 26; 4.1 mm. pepsin. Gastric contents contained a great deal of mucus.

CASE 4.—Patient, F. S., female; age 37; born in Russia. Dr. David Riesman permitted me to examine this patient. Diabetes mellitus; lacerated cervix and perineum. Glucose in urine from + to 7 per cent.

Feb. 16, 1909: Ewald test breakfast aspirated in thirty minutes; 20 c.c.; total acidity 76; free hydrochloric acid 36; 2. mm. pepsin.

CASE 5.—Patient, D. C., female; aged 40; born in Russia. Kindly sent to me by Dr. David Riesman. Glucose in urine 2.35 per cent.

Dec. 1, 1909: Patient ate a full dinner at noon. This not being known, she was given an Ewald test breakfast at 1.45 p. m. Aspirated in forty minutes; 15 c.c.; total acidity 27; no free hydrochloric acid; pepsin 2.4 mm.

Dec. 8, 1909: Full dinner at 1 o'clock; aspirated at end of one hour and forty minutes; 30 c.c. very thick contents containing a great deal of mucus; total acidity 40; no free hydrochloric acid; pepsin 2.1 mm.

CASE 6.—Patient, C. L., female; aged 56; born in Russia; kindly sent to me by Dr. A. A. Eshner. Glucose in urine, 3.75 per cent.

Aug. 29, 1910: Full dinner, aspirated at end of two hours and forty minutes; 20 c.c.; total acidity 50; no free hydrochloric acid; no pepsin.

Ewald test breakfast, aspirated after thirty minutes; 10 c.c.; total acidity 46; no free hydrochloric acid; no pepsin.

CASE 7.—Patient, S. B., male; aged 21; born in Russia; kindly sent to me by Dr. A. A. Eshner. Glucose in urine 4.16 per cent.

Ewald test breakfast: aspirated after forty-five minutes; 45 c.c.; total acidity 86; free hydrochloric acid 50; pepsin 0.1 mm.

Full dinner: aspirated after two hours and forty minutes; 300 c.c.; total acidity 66; free hydrochloric acid 48; no pepsin.

Ewald test breakfast: aspirated after thirty minutes; 10 c.c.; total acidity 90; free hydrochloric acid 50; no pepsin.

Full dinner: aspirated after three hours; 40 c.c.; total acidity 99; free hydrochloric acid 50; 0.1 mm. pepsin.

Full dinner: aspirated after three hours; 1 pint; total acidity 96; free hydrochloric acid 60; 0.1 mm. pepsin.

TABLE OF EXAMINATIONS *

Case No.	Patient	Tests No.	Pepsin† +	—	T. A.	Free HCL	Pepsin mm.
1	L. W.	.	.	.	90	48	‡
2	A. C.	6	1	5	10	0	2.7
3	H. C.	2	2	.	44	28	4.1
4	F. S.	1	1	.	76	36	2.0
5	D. C.	2	2	.	27	0	2.4
6	C. L.	2	.	2	40	0	0.0
7	S. B.	5	3	2	99	60	0.1

* No lactic acid present in any case.

† Plus column, number of times present; minus column, number of times absent.

‡ Not determined

The total acidity and the amount of free hydrochloric acid were also determined, and tests were made for lactic acid when free hydrochloric acid was absent. No lactic acid was found. The total acidity was high in three cases and the free hydrochloric acid was high in four. Hydrochloric acid was absent in three.

It has been shown by Riegel and others that hydrochloric acid may be absent from the stomach contents for long periods of time in this disease and then reappear. Honigmann ascribed the lack of free hydrochloric acid to the increased motility of the stomach. Rosenstein was of the opinion that if free hydrochloric acid was permanently absent, it was due to atrophy of the glandular apparatus of the stomach, caused by interstitial inflammation of the gastric mucosa. Autopsy on these latter cases, however, failed to prove this view to be correct.

It is also believed that in those cases in which there is a temporary absence of free hydrochloric acid in the stomach contents the cause is a neurosis. As most of these patients have arteriosclerosis, it is possible that this condition may also have a part in the stomach functions in this disease.

In the few cases here reported it is shown that the absence of free hydrochloric acid in diabetes mellitus, as in other diseases, does not mean an absence of pepsin. On the other hand, it is also shown that a high percentage of hydrochloric acid does not indicate a good pepsin digestion.

A pepsin digestion of between 3 and 4 mm. is in my experience about the average in non-diabetic patients.

While one cannot draw any general conclusions from a small number of cases, it may be said that secretion of pepsin in diabetes mellitus is frequently reduced and sometimes absent; this observation may be added to the facts already mentioned and long known; i. e., the gastric motility is usually increased and the gastric secretion is frequently diminished in this disease.

In conclusion I wish to thank Drs. Eshner and Riesman for sending their patients to me for study and Dr. Farr for permission to examine them in his clinic.

1934 Chestnut Street.

THE ADVANTAGES OF NITROUS OXID-OXYGEN ANESTHESIA ESPECIALLY IN CONNECTION WITH ULTIMATE RECOVERY *

RAYMOND C. COBURN, M.A., M.D.
NEW YORK

As the aim of the surgeon is to record a "successful operation," not only from a scientific point of view, but from the patient's standpoint as well, the selection and administration of the anesthetic becomes more and more a matter for consideration as this branch of medical science is developed.

Until recent years the dangers of the anesthetic were considered solely those occurring on the operating-table, but laboratory investigation has established, beyond the possibility of a doubt, that a percentage of surgical mortality, heretofore considered to be due to the patient's condition, effects of the operation, etc., is sometimes due directly to the effects of the anesthetic, even though death occurs remotely from the time of the operation. Careful and extended clinical observation on nitrous oxid-oxygen anesthesia in several thousand cases, by some of the most talented surgeons of this country, completely verifies this conclusion.

The use of nitrous oxid as an anesthetic agent presents an interesting and a very peculiar history, which I shall not attempt to detail here. To Andrews, of Chicago, belongs the credit of discovering that by the addition of the proper amount of oxygen, the asphyxial symptoms of nitrous oxid are prevented without destroying its anesthetic properties.

Since this discovery was made, over forty years ago, nitrous oxid-oxygen has slowly, intermittently, but very persistently gained recognition until to-day it occupies the meritorious position of being endorsed by one of the largest and greatest scientific societies of the world, as being, all effects considered, the best means for producing anesthesia that is known.

There is a prevalent idea that nitrous oxid-oxygen is better adapted for minor surgery and short operations than for major work. This is an erroneous impression, however, for the longer this anesthesia is maintained, the better it becomes in every way. I myself have administered it throughout practically the whole range of operative procedure from a simple incision to difficult and complicated operations lasting over four hours, which is the longest period, as far as I know, wherein this anesthetic has ever been continuously administered. Dr. Frederick Hewitt, of London, a leading authority on anesthetics, says:

> There is no form of anesthesia at present known which is so devoid of danger as that which results from nitrous oxid when administered with a sufficient percentage of oxygen to prevent all asphyxial complications.

The Anesthesia Commission of the American Medical Association reported at its last session in St. Louis as follows:

> As a routine anesthetic nitrous oxid has a peculiar value, . . . (and) in the hands of highly skilled anesthetists the method is the best yet devised.

These statements are corroborated by such practical surgeons as Crile, Meyer, Kelley, Halsted and Bevan, who collectively have certainly used it in thousands of cases, and are therefore in a position to express an opinion of value as to its superior influence toward ultimate recovery.

There is much less surgical shock and postanesthetic nausea and depression with nitrous oxid than with ether or chloroform; the patient regains consciousness very quickly, and, being less depressed, recovers from the effects of the operation sooner and better.

Hamburger and Ewing, who have made an extended laboratory investigation of the effects of the narcosis produced by nitrous oxid, chloroform and ether on the blood, and whose findings are published as a part of the preliminary report of the Anesthesia Commission of the American Medical Association, say, as regards ether:

> The color index shows a rather constant drop, starting immediately after anesthesia and reaching its lowest point on the fifth and sixth days. This would indicate a relative loss of hemoglobin per cell, and again is unlike nitrous oxid results, in which the only sign of a low color index is found immediately after the anesthetic mask is removed, and which is completely gone in two hours.
>
> The volume index likewise shows an immediate loss, which is most marked in twenty-four hours, and again on the fifth to seventh days. In nitrous oxid readings the percentage volume remained unchanged throughout.

According to these investigators so short an anesthesia as fifteen minutes with ether causes a definite and demonstrable anemia, and such an effect as this, which does not begin to improve till after the fifth day, must certainly retard convalescence even in favorable cases, and in critical cases may be the determining factor in producing a fatal termination.

Chloroform produces even more destructive changes on the blood than does ether, while its degenerative action on the liver has been mentioned by so many writers that this serious and remote effect needs merely to be mentioned here.

For some time it has been recognized that ether increases the toxemia arising from infection. Recent investigation shows that this is due to the fact that ether impedes the functional activity of the leukocytes: that is, it lessens the patient's resisting power against the infection, whereas nitrous oxid exerts no such injurious effect on the blood-cells, and consequently does not lower the patient's immunity, which naturally exists. In serious cases of infection, as well as in the "borderland" cases in general, the difference in ultimate recovery under the two anesthetics is strikingly shown.

Numerous surgeons have advised against the use of ether in tuberculous conditions, as, in their experience, it causes new foci of infection to develop. This, however, is only a particular instance of the general effect produced, for, no matter what the infection may be, the toxic effect of ether on the leukocytes lessens the efficiency of Nature's effort to combat the invading host.

As is well known, ether is an irritant to the respiratory mucous membrane and to the kidneys, whereas

---

* Read before the New York Academy of Medicine, Section on Orthopedic Surgery, Nov. 18, 1910.

nitrous oxid is without deleterious effect on these tissues, and is therefore strongly indicated as the anesthetic agent whenever these structures are involved, no matter what the operation may be, as in tuberculosis, pneumonia, bronchitis, laryngitis, nephritis, diabetes, pyelitis, and a host of other inflammations and infections of the respiratory and genito-urinary tracts. In fact, when you take into consideration the lessened amount of surgical shock and of postoperative discomfort and depression, the absolutely non-irritant action on the mucous membranes of the tracts involved in its administration and elimination, and the blood elements left unimpaired, its range of usefulness is so broad that it should be the anesthetic of choice, except in instances in which it is specially contra-indicated. Besides, when this anesthetic is used, there is less liability of infection occurring during, or subsequent to the operation, inasmuch as the patient is less depressed, and natural immunity undisturbed. These are practical points which every operator should carefully consider, as they are important elements, no matter how trivial each may at first appear, when considered separately, for, taken collectively, they most certainly affect the postoperative condition in every case.

It is readily granted that in the hands of the skilled anesthetist there is very little immediate danger in the use of the other anesthetics, and that, in such hands, the immediate mortality is very low indeed; but is it fair to conclude that the remote effects, much more subtle in their influence, and therefore much more difficult of detection, are consequently *nil?* Take, for instance, a case of grave infection; one of the other general anesthetics is faultlessly administered, but the surgeon's mortality is increased, and every surgeon of wide experience encounters some such cases. In the light of this research can it be said that the anesthetic did not contribute to the fatal result, or that the patient might not have been saved had a less toxic and less depressing agent, and one which did not lessen the patient's natural resisting power, and decrease the life-sustaining function of the blood-cells, been used? It is not contended that this form of anesthesia saves all patients of this class, but, in the language of Crile, "Not a patient showed the rapid march to fatality immediately following the operation which occasionally follows ether." Why the conspicuous absence of that "rapid march to fatality?" Simply because the patient is given a new and firmer hold on life, enabling some to recover that otherwise would simply increase the mortality. I very readily assent to the observation of Gatch that "very sick patients, with a rapid pulse and quick, shallow respiration, actually seem benefited by this form of anesthesia." That is, such patients will, during an operation under this anesthesia lasting for forty-five minutes to an hour, manifest a distinct improvement in the rate and quality of the circulation and respiration, both during and subsequent to the operation, the effect being quite permanent, as it is not a mere stimulant.

From the patient's point of view the lessened amount of postoperative discomfort alone is sufficient to call for this anesthetic, as he usually dreads the subsequent nausea, vomiting and depression more than the effects of the operation itself. Besides, when a patient can be told that he is simply to be given "laughing-gas" it allays to a very great extent the fear and dread of the anesthetic, and many patients will submit to operations under this agent who would otherwise refuse all operative intervention.

It is a matter of no little comfort to the patient and to his family to know that complete consciousness returns so quickly after the operation is completed, and especially is this so, when, as in the majority of cases, there is freedom from postnarcotic discomfort, and a pleasant impression is left on the mind by the "laughing-gas." For a patient to be returned from the amphitheater to his own room completely conscious, smiling and talking to his nurse and friends, even after a prolonged operation, presents a different picture from that usually seen with other anesthetics, and gives a distinct advantage in convalescene. I cite just one case to illustrate: Dr. X. of a neighboring state was anesthetized for a rectal operation, necessarily requiring deep anesthesia. Within a very short time after the administration of the anesthetic was stopped he opened his eyes and said with a smile to those in attendance: "Well, if you folks had as good a time as I did, you certainly enjoyed this operation." He had had a dream about being at a big fire. Some time afterwards he said in a private letter to me: "You simply make anesthesia a pleasure." To have an intelligent patient, and especially a practitioner of wide experience, consider the taking of the anesthetic as a genuine pleasure is certainly valuable testimony to the great advantage offered by this anesthetic.

It is almost imperative to use a preliminary hypodermic injection of morphin and atropin about one-half hour before the time of the operation, as this medication aids very materially in securing muscular relaxation. Besides, the patient recovers from this anesthesia so quickly that it is usually indicated for the postoperative pain alone. When it is used the patient's nerves are quieter and he approaches the operation with more confidence and less fear—an important element in every case. In that class of patients or operations, in which it is difficult to overcome muscular rigidity the addition of a very small amount of ether—not sufficient to give the ether after-effects—in conjunction with the nitrous oxid and oxygen will secure the necessary relaxation. Used in this way, nitrous oxid-oxygen is a pleasant anesthetic for even the most fastidious patient, fulfils the requirements of both minor and major surgery, and produces the lightest and least toxic general anesthesia yet discovered.

PRIMARY SARCOMA OF THE STOMACH WITH AUTOPSY FINDINGS *

O. W. H. MITCHELL, M.D.
COLUMBIA, MO.

Sarcomas of the stomach are rare, and, beyond the mention of this fact one finds little discussion of the subject in most text-books of pathology. Therefore, all cases which are substantiated by microscopical study should be reported so that our knowledge regarding the pathology and symptomatology of this condition may be increased. For these reasons I report the following case:

History.—The patient, E. R., a white woman aged 72, was in the services of Drs. J. E. Thornton and M. D. Lewis, of Columbia, Mo., and the following history was given me by the former. The patient's husband died of cancer of the face. She had been healthy until two years ago when she began to decline. About one year ago she began to suffer pain in the region of the spleen which gradually increased. She had been in bed only about one month. A tumor mass was palpable in the epigastric region. The patient was very anemic but quite fleshy. The clinical diagnosis was cancer.

---

* From the Pathological Laboratory, University of Missouri.

Necropsy.—Woman, well preserved for her age. The hair of the head and pubis was gray. The skeletal system was moderately heavy and the musculature was light. The subcutaneous layer of adipose tissue was quite thick and of a good color. All of the thoracic and abdominal viscera were normal except the stomach. Involving the pyloric end of the stomach was an annular tumor measuring 5 inches in diameter and ½ an inch thick in places. The diffused tumor was covered with mucous membrane except for a surface measuring about 2 inches in diameter. The tumor was very firm and the cut surface was smooth and glistening white in color. There were no evidences of metastatic growths in the lymph-nodes or in any of the organs. Although the patient did not look especially "cancerous" and the gross findings were far from being typical for such a condition, a provisional diagnosis of carcinoma of the pylorus was made. The microscopic examination showed the tumor to be a small round-cell sarcoma. There was little stroma and many mitotic figures were present. In sections showing the mucous membrane the tumor cells could be seen invading the subepithelial connective tissue.

A good article on sarcomas of the intestinal tract with splendid compilation of statistics was written by Corner and Fairbank.[1] In the 178 reports of cases collected from the literature, fifty-eight cancers were of the stomach. There was only one portion affected more. the small intestines. There were sixty-five occurring in this region. Corner and Fairbank found the cases about equally divided as to sex, males twenty-six, females twenty-nine. The most common age was between 40 and 50 years. The youngest patient was 3½ years old and the oldest 78. They found 36 per cent. located at the pylorus. About 60 per cent. of gastric carcinomas are located at the pylorus. The following points given by them might be of value in differentiating sarcoma from carcinoma of the stomach: "The rapid course with marked anemia, the absence of hematemesis or gastric dilatation, the presence of a large tumor, and, possibly, the age of the patient." Of fifteen patients operated on. four were reported living after four, five, twelve and twenty-four months respectively since operation.

THE ADMINISTRATION OF SALVARSAN

DOUGLASS W. MONTGOMERY, M.D.
Professor of Diseases of the Skin, University of California
SAN FRANCISCO

One-third by weight of salvarsan is arsenic, and therefore in administering 0.6 gm., which is an ordinary dose, we are giving the patient 0.2 gm. of arsenic, or fifty times the amount that in the usual pharmaceutic combinations would cause poisoning. It is through the genius of Ehrlich that a way has been found to give this enormous dose, and almost always without causing any disagreeable symptoms, with the exception of pain—and even pain may be eliminated by injecting the drug intravenously. That great care must be observed in giving it goes without saying.

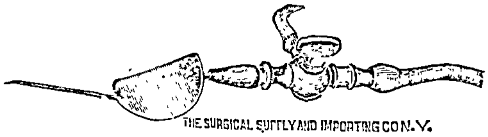
The drug is put up as a dry powder, enclosed in glass tubes, and in this form is stable; at least I have never yet heard of any trouble arising from its decomposition in the tubes. In solution, however, it quickly decomposes; in simple water it forms an acid solution that lasts undecomposed for several hours, probably for a day. As an alkaline solution, however, it quickly decomposes, and shortly turns wine red. The drug is administered either suspended in oil or as a solution, and must be made up fresh at each time of using. I have never seen it suspended in oil, but Neisser has so given it, and has advised oil of sesame as the best oily medium.

The acid watery solution of the drug is very painful when injected, and should first be made either alkaline or neutral. The care and trouble attendant on dissolving, alkalinizing, and again neutralizing the drug, and the further trouble of injecting it either subcutaneously, intramuscularly, or intravenously, and the pain, and occasional local necrosis caused when given subcutaneously, have impelled clinicians to adopt numberless modifications in technic. The best results I have seen, however, have been attained by comparatively simple methods.

THE INTRAMUSCULAR INJECTION OF SALVARSAN

Alt was the first to employ the drug clinically, and his method, as I have seen it in Lesser's clinic, is painful, as all these methods are, but it is simple and effective, and has not up to the present, in Lesser's hands, caused necrosis or abscesses. He has so used it in a great many cases, but he always taps wood when he speaks of his good luck.

He first takes salvarsan, 0.5 or 0.6 gm., and warm water, 5 or 6 c.c., and mixes them together in a glass-stoppered, graduated glass cylinder with glass balls to facilitate solution. He then adds 3 c.c. of sodium hydroxid (4 per cent. sol.), and again shakes well, adding drop by drop more of the sodium hydroxid solution till the solution in the glass cylinder is nearly clear. Normal salt solution may be added up to the 10 c.c. mark, and this is then injected into the gluteus. This should not be repeated before four or six weeks have elapsed.



Needle used by Schreiber, having a bayonet bend in the shaft with a ribbed finger-hold for guiding the needle in intravenous injection, together with the two-way cock betweeen the needle and the barrel of the syringe.

The same solution may be injected subcutaneously, usually under one or other shoulder-blade. There is, of course, more risk of an ensuing necrosis when injecting subcutaneously, than when injecting intramuscularly into the gluteus. The gluteus seems to be especially fitted to receive insults.

THE INTRAVENOUS INJECTION OF SALVARSAN

If Ehrlich's ideas in regard to the sterilization of the body are to be carried out, there is no doubt that the intravenous is the only correct method of administering salvarsan, as in neither the subcutaneous nor the intramuscular method is it possible to tell how soon the dose will be absorbed. By the intravenous method the medicine is given in a manner that insures the rapid diffusion of the full dose, without running the risk of ensuing necrosis, or abscesses, or of chronic arsenical poisoning from prolonged absorption. As far as pain is concerned, there is only the insignificant prick of the needle

---

[1] Corner and Fairbank: Practitioner, 1904, lxxii, 810.

22895

At the kind suggestion of Professor Ehrlich I went to Wiesbaden to see Professor Weintraud, and to Magdeburg to see Dr. Schreiber. The only practical difference between these two is that one employs pressure by gravity, while the other uses a specially constructed syringe. I shall give Dr. Schreiber's method, as it seemed to me to be superior in some rather important details.

THE PREPARATION OF THE SOLUTION FOR INJECTION

About 20 c.c. of warm distilled water are poured into a graduated glass cylinder of a capacity of 250 c.c. This cylinder should have a glass stopper.

The glass capsule containing the salvarsan powder is now wiped off with gauze soaked in alcohol, and then with gauze soaked in ether. After breaking the capsule, the powder is poured on the water in the graduated glass tube, the stopper put in, and the contents well shaken. There is no necessity of using glass balls here, as the quantity of water is ample to dissolve the salvarsan readily.

It is important not to reverse this procedure, for if the powder is poured into the tube first, and the water afterward, a gummy mass forms in the bottom that dissolves with difficulty. This solution should be light yellow, and perfectly clear. That it should be clear is a matter of very great importance, as it is highly necessary that no undissolved particles be present.

Now we have an acid solution in sterilized water of the contents of one tube, the quantity of which is usually 0.5 or 0.6 gm. If it is 0.5, the graduated tube should be filled up with water to the 50 c.c. mark; if 0.6, to the 60 c.c. mark, so that each 10 c.c. will represent 0.1 of the drug.

Dr. Schreiber usually gives 0.3 gm. of salvarsan to a woman, and 0.4 gm. to a man. If it is desired to give 0.4 he pours 40 c.c. of the acid solution into another graduate furnished with a glass stopper, and fills up to the 200 c.c. mark with warm sterilized water, and to this adds about 20 c.c. of normal sodium hydroxid solution. Normal sodium hydroxid solution is a 4 per cent. solution of sodium hydroxid in water. This should be added a little at a time, and each time a little is added the glass stopper should be put in, and the cylinder well shaken. At first a precipitate forms, that gradually disappears on the addition of more caustic soda solution. When the solution is again clear, it is alkaline and ready for injection.

The flask containing the sterilized distilled water for use in making the solutions should not be stoppered with cotton, but with gauze, as cotton fibers, falling into the fluid, might cause trouble.

SYRINGE FOR INJECTING

The best syringe for injecting is a glass Lüer of about 20 c.c. capacity. It should not have a metal plunger, as in that case the least blood may cause binding. A two-way cock is introduced between the needle and the barrel.

Dr. Schreiber has a special needle made with a bayonet bend in the shaft, and on this bend a ribbed finger-hold. The bayonet bend is to allow the needle to be more easily shoved along in the lumen of the vein. A rubber tube is fitted to the lateral outlet of the two-way cock.

INTRODUCTION OF THE NEEDLE

The arm is now laid out on a cushion, so as to lie flat and easy; a stout rubber tube is thrown around the middle of the upper arm and drawn tight enough to stop the flow of blood in the superficial veins, but not so tight as to impede the arterial supply, and fastened with artery forceps or a wooden clip. It is very necessary that the arm should lie easy and still. The seat of operation should be wiped off with gauze soaked in alcohol.

About 4 c.c. of normal salt solution are drawn into the syringe, so that by running the plunger forward the air may be expelled from the needle and from the rubber tube attached to the outlets of the two-way cock.

Now the needle is inserted through the skin over a vein, and run along into the vein. When the needle enters the vein a little blood flows back into the normal salt solution in the syringe. If the plunger is pressed forward, the salt solution entering the vein will distend it a little, and when it does so, the tourniquet band about the arm may be removed, and the vein will collapse.

The insertion of the needle is a very important step in the operation. For instance, by blood flowing back into the syringe, it is known that the needle has entered the vein. Weintraud insists that the blood should flow freely from the needle, but in his method the needle is first inserted into the vein, and afterward the rubber tube conveying the salvarsan solution from the funnel-like cylinder, is attached to it.

The syringe, still containing a little salt solution, and with its needle lying in the vein, is now ready for injecting the fluid, which is held in a glass beaker so that the rubber tube attached to the lateral opening of the two-way tap drops into it. The instrument is free of air so that there is no fear of air embolus. By turning the cock of the two-way tap, the salvarsan solution may be alternately sucked up into the syringe, and forced into the vein. When the salvarsan solution is almost exhausted, a little normal salt solution is thrown into the beaker, and also injected into the vein. This is to clear away any of the salvarsan solution that would otherwise trickle out into the tissues, on withdrawing the needle.

A very important matter in this part of the operation is the injection of the small quantity of normal salt solution, both before and after injecting the salvarsan. By injecting the normal salt solution at first, one makes sure that the needle is in the vein, for if it is not in the vein, the injected fluid makes a little infiltration in the subcutaneous tissue, while if it is in its proper position, the already distended vein grows a little larger. If this sign should fail, there is still a symptom showing that the needle is not in place, for as soon as a little of the salvarsan enters the subcutaneous tissue the patient will experience a burning pain, in which case the needle should be immediately withdrawn, and free bleeding induced from the punctured wound. Another vein should then be chosen for the injection. Any subcutaneous vein that can be distended may be chosen, and in fleshy women Dr. Schreiber has even injected into one at the wrist. Sometimes when the vein cannot be seen, it may be felt.

The fluid should be injected slowly, say in five or six minutes, so as to avoid sudden overloading of the circulatory system.

Although the description of the operation is long, tedious, and complicated, yet the performance is very simple, and the patients experience very little inconvenience. They should remain twenty-four hours in bed.

When I was in Magdeburg Dr. Schreiber had given intravenously one dose of salvarsan to each of 155 patients; he had given two doses to each of 622 patients; and intramuscularly he had given one dose to each of 83 patients; making a total of 860 patients treated. Up to that time, he told me, he had had no serious trouble consequent on the use of the drug, and this statement, from what I have seen of his clinic and his personality, I fully believe. That trouble may follow the use of this remedy goes without saying; we are dealing with arsenic.

Whichever method is adopted, all instruments should be carefully sterilized as the irritant metal and germs make a highly septic combination. Salvarsan is probably no more antiseptic than Fowler's solution, in which, as is well known, fungi will grow freely.

In making the solution, glass stoppers should be used for the cylinders, as cork stoppers in contact with sodium hydroxid solution make a brown fluid, which at least looks dirty.

If it is desired to neutralize the fluid for injection after it is alkalinized with sodium hydrate solution, this is best done by adding, drop by drop, a 1 per cent.

glacial acetic acid solution. The neutral point may be determined by letting a drop of the fluid fall from the tip of a glass rod on litmus paper.

If the more concentrated solution for intramuscular injection is desired, and glass balls are not obtainable, the powder may be rubbed up with water in a mortar. The glass balls, however, are preferable.

THE TREATMENT OF DRUG ADDICTION

ALEXANDER LAMBERT, M.D.
NEW YORK

The statements which I made in my former article[1] concerning the efficacy of the treatment to obliterate the craving for narcotics have been confirmed, and this treatment is to-day the most successful method which I have yet found for the obliteration of the craving for morphin, opium, cocain, alcohol, or tobacco. I have endeavored to simplify the method, and have succeeded in some measure; the same combination of drugs is used, and only the details of their administration have been changed. The plan which I have found to be most effective, and most easily followed by others, is as follows:

The belladonna mixture of two parts 15 per cent. tincture of belladonna, and one part each of the fluid extracts of hyoscyamus and xanthoxylum, has proved itself an essential part of the treatment. When the 10 per cent. tincture of belladonna has been used, or when even a 12 per cent. tincture has been employed, the results obtained were not clear-cut, but left the patients with an indefinite nagging longing for their narcotic. It seems necessary to push this mixture to the physiologic tolerance of the belladonna. This tolerance, of course, varies with the individual, and some of the best results have been obtained with patients who could not tolerate as an hourly dose more than from 2 to 4 drops of this mixture while others easily tolerated from 18 to 20. It would seem, judging from clinical results, that there are some properties in this mixture which are necessary to a successful carrying out of the treatment. The bottle containing this mixture must be kept well corked, and shaken before using. The method which I now pursue is as follows:

A patient addicted to morphin is given five compound cathartic pills and 5 grains of blue mass, and six hours later, if these have not acted, they are followed by a saline; after three or four abundant movements of the bowels from these cathartics, the patient is given, in three divided doses at half-hour intervals, two-thirds of the total daily twenty-four-hour dose of morphin or opium to which he has been accustomed. Observe carefully after the second dose has been given, as the amount then equals four-ninths or nearly one-half the total twenty-four-hour dose. Some few patients cannot comfortably take more than this amount. At the same time with the morphin, 6 drops of the belladonna mixture is given in capsules. This belladonna mixture in doses of 6 drops (and by drops I do not mean minims, I mean drops dropped from an ordinary medicine dropper, which is about half a minim dose) is given every hour for six hours. At the end of six hours the dosage is increased 2 drops. The belladonna mixture is continued every hour of the day and every hour of the night continuously throughout the treatment, increasing 2 drops every six hours until 16 drops are taken, when it is continued at this dosage; it is diminished or discontinued at any time if the patient shows belladonna symptoms such as dilated pupils, dry throat or redness of the skin, or the peculiar and incisive and insistent voice, and insistence on one or two ideas. It is begun again at reduced dosage after the above symptoms have subsided.

At the tenth hour after the initial dose of morphin is given, the patient is again given five compound cathartic pills, and 5 grains of blue mass. These should act in six or eight hours after they have been taken. If they do not act at this time some vigorous saline is given, and when they have acted thoroughly the second dose of morphin is given, which is usually about the eighteenth hour. This should be one-half the original dose; i. e., one-third of the original twenty-four-hour daily dose. The belladonna mixture is still continued, and ten hours after the second dose of morphin has been given, that is about the twenty-eighth hour, five compound cathartic pills are again given and 5 grains of blue mass, these again if necessary followed by a saline seven or eight hours later. At times when the C. C. pills are not acting well, or too slowly, five or six "B. B." pills are given from two to three hours after the C. C. pills. These "B.B." pills are the pilulæ catharticæ vegetabiles of the Pharmacopeia with 1/10 gr. oleoresin of capsicum, ½ gr. ginger, and 1/25 m. of croton oil added to each pill. After these have thoroughly acted at about the thirty-sixth hour, the third dose of morphin is given, which is one-sixth of the original dose. This is usually the last dose of morphin that is necessary. Again, ten hours after this third dose of morphin, i. e., the forty-sixth hour, the five C. C. pills and 5 grains of blue mass are again given, followed seven or eight hours afterward by a saline, and one expects at this time to see the bilious green stool appear. When this appears, after the bowels have moved thoroughly, ten or twelve hours after the third dose of morphin, about the fifty-sixth hour, 2 ounces of castor oil are given to clear out thoroughly the intestinal tract. During this last period when the bowels are moving from the C. C. pills and before the oil is given, the patients have their most uncomfortable time. Their nervousness and discomfort can be controlled usually by codein, which can be given hypodermically in 5 grain doses and repeated if necessary, or some form of the valerianates may help them. About the thirtieth hour these patients should be stimulated with strychnin or digitalis, or both. After they are off their drug, I have found that the tonics which do them the most good are those which contain some form of phosphorus and arsenic, and I must reiterate as before the danger of these patients overeating, and thus bringing back all their withdrawal symptoms due to the disturbance of digestion. They have been in the habit of referring all uncomfortable feelings to those of the withdrawal symptoms of morphin, and digestive disturbances feign these withdrawal symptoms. Sometimes about the thirty-sixth hour the stools became clay-colored. Some form of prepared ox-gall is most effective to stimulate further biliary secretion given in small doses every hour for five or six doses.

In treating an alcoholic, the belladonna mixture and the five C. C. pills and 5 grains of blue mass are given simultaneously at the first dose. The belladonna mixture is continued every hour of the day and every hour of the night the same as with the morphin patients, and twelve hours after the initial dose patients are again given from three to five C. C. pills, and at the twenty-fourth hour after the initial dose, they are again given the cathartics followed by salines if necessary, and again at the thirty-sixth hour. After these last cathartics, the bilious stools will appear, and by the forty-fourth or forty-fifth hour the castor oil is given. Sometimes it is necessary to carry on the treatment over another period, and the C. C. pills and blue mass are again given at the forty-eighth hour, which would bring the end of the treatment about the sixtieth hour.

---

[1] The Obliteration of the Craving for Narcotics, The Journal A. M. A., Sept. 25, 1909.

Elderly or very nervous patients who have been on a prolonged debauch are tapered off with 2 ounces of whiskey for four or five doses through the first twenty-four hours. If these patients are excessively nervous it is necessary also to see that they sleep, and the mixture of chloral hydrate, gr. xx, morphin, gr. 1/8 tincture of hyoscyamus dram 1/2, ginger m. x and capsicum m. v, water 1/2 ounce, which was recommended before is the best hypnotic for them. These patients should also have cardiac stimulants such as strychnin and digitalis after the first twenty-four hours, sooner if they are weak. If the patient has an alcoholic gastritis and cannot retain medicine, it is wise to give him 5 grains of Tully's powder (pulvis morphinæ compositus) with 5 grains of sodium bicarbonate about every two hours for two or three doses, as this seems to be the most effective method of allaying the vomiting of an alcoholic gastritis.

The cocainist can be treated like the alcoholic, except that no cocain is given at any time, and strychnin or some such stimulant must be given from the beginning of the treatment.

I have often been asked as to the permanency of this treatment, and I can but repeat that most morphinists desire to be rid of their addiction and that when once the withdrawal symptoms are passed and the craving for the drug has ceased, they are only too glad to be free from their slavery. If the cause for which they originally took the opiate is removed, in the majority of cases they will not return to their drug. With the alcoholic it is different, although this treatment is the best one I have yet found to eradicate thoroughly and in a short time all desire for alcohol and to stimulate him mentally and leave him in a condition in which he can exist without his customary stimulant. Alcoholism is a social vice and not a secret one, as is morphinism. Most men cannot bring themselves to realize that they cannot take a single drink and cannot drink in moderation as they see other men do, and it sometimes takes two or three bitter lessons before they are willing to acknowledge this to themselves. When once they realize it and acknowledge it to themselves as well as to others, they will not take alcohol, but there is no compromise with them. They cannot take a single drink of any form of alcohol without the danger of going back to alcoholic excess.

Since publishing my first article I have treated many patients addicted to morphin, cocain and alcohol, and the results obtained with these patients, as well as the reports from many sources obtained through an enormous correspondence, have confirmed me in my conviction that this treatment will more effectually obliterate the craving for narcotics, in the shortest time and leave the patient in better condition to recuperate to vigorous health, than any other treatment that has yet come to my knowledge. It is a treatment of many details which must be adhered to if success is to follow. But my experience justifies me in saying that if these details are adhered to, success will follow.

A GROUP OF SYPHILITIC PATIENTS TREATED WITH SALVARSAN (EHRLICH-HATA 606)

OLIVER S. ORMSBY, M.D.
CHICAGO

This group of cases includes chiefly those of dermatologic interest. At the time the work was done, the method of administration as recommended by most experimenters was by subcutaneous injection of an emulsion of the drug according to the Wechselmann method. After the first group of injections had been made subcutaneously in emulsion by this method, Dr. Flexner requested that the intramuscular method be employed, using a solution according to the method of Lesser. The second injection given in Case 7 and the one given in Case 8 were therefore made in this manner.

The cases included a well-defined macular, a papulopustular, a corymbose, a large flat papular, a deep gummatous (bones and deeper tissues) and an ordinary gummatous syphiloderm, and two in which early nervous lesions were exhibited. The patients were all examined for any contra-indications relative to heart, lungs, kidneys, etc., by Dr. Joseph L. Miller, and as to eye complications by Dr. E. V. L. Brown. This work was controlled by the Wassermann reaction repeatedly made, and by blood-counts; and finally was undertaken with the view of ascertaining the result obtainable with a single injection of a comparatively large dose of the drug. They have been under observation for more than three months, so we can now determine what the result is with a single dose in these cases. I am indebted to Dr. H. J. Nichols and Dr. Simon Flexner for the material (drug) used, and to Dr. J. Frank Waugh for valuable assistance in the preparation of the remedy and making the Wassermann reactions, and Dr. Nilsson, House Surgeon at the County Hospital, for assistance in many ways.

In view of the enormous literature already at hand, it is my purpose only to record results, as it is by the accumulated results in patients actually treated in many parts of the world, that deductions will finally be drawn both as respects the drug itself and its method of administration.

Most of these patients were treated at the County Hospital, where they were entered in my service, and most of them remained two months or more to complete the preliminary observations.

REPORTS OF CASES

Case 1.—Gummatous and ulcerative syphilis (hereditary). M. W., a woman aged 23, entered the Cook County Hospital Oct. 18, 1910; duration of the disease in its present form, twelve years.

History.—The patient was apparently healthy until twelve years previously, when (as stated by the patient) following vaccination the lesions to be described began to appear. During the twelve years the lesions had periods of activity and retrogression. Ulcers appeared and healed, with new ones occurring. The distribution was fairly general. Head, face, arms and limbs had all been attacked and the deformity was marked and characteristic. The bones in all of these regions showed deformity.

Examination.—At the time of administration of salvarsan the patient presented the following appearance: Small, elderly-appearing, with scars, ulcers, deep nodules and discharging sinuses over most of the body; mentality below par.

Regional:

Head: The entire scalp presented a mass of deep ulcers, pus-discharging sinuses and heavy crusts. In many places bone involvement was evident. The face presented deep funnel-shaped openings, extending on the right side into the malar bone; a similar lesion present on the left side; marked ectropion of right lower eyelid due to contracture from a scar below. Eyes: Pupils small, but reacted normal; negative otherwise. Mouth: Palatal arch high and narrow. Teeth: Several missing, remainder more or less loose and carious. Nose flat and depressed; nasal septum eroded. Neck: Enlarged glands on either side.

Trunk and Genitals: No cutaneous or deeper lesions.

Upper Limbs: Bones of both forearms deformed; irregular deep depressions present, many scars and ulcerated areas, and some deep sinuses; joints enlarged, deformed and limited in motion; small joints of hands also involved; glands of axillæ enlarged.

Lower Limbs: Tibiæ deformed. Typical deformity of bones (enlarged and bowed); large ulcers and deep sinuses on both sides; a typical luetic ulcer present in right ankle the size of one's palm.

Urine: Cloudy, straw-colored, specific gravity 1.021, acid in reaction; albumin present abundantly; no sugar; microscopic examination revealed granular casts, a few epithelial cells and a few leukocytes; no erythrocytes; mucus moderately present. Wassermann, October 19, +++.

October 20, 0.45 gm. salvarsan was injected beneath scapulæ, dividing the dose into two parts, one-half given on either side.

General examination revealed no particular contra-indications. The patient had been habitually restless and sleepless at night.

Progress and Comments.—The urinary findings under some conditions would have been a contra-indication for the treatment, but in view of the probable luetic kidney involvement, it was not so considered in this case. The progress toward recovery following this injection was remarkable. No local reaction of moment occurred. There was a very moderate systemic reaction. After the first night the patient slept well and rapidly gained in weight. Her mental condition changed from that of a dull, morose individual to a happy, smiling and much younger-appearing woman. Pain entirely ceased; ulcers and sinuses healed and clinically the patient recovered rapidly. The Wassermann reaction remained strongly positive throughout the entire period of observation. Three months after the injection the patient had not entirely recovered, for a few small lesions remained. At this time more treatment was indicated. The Wassermann record is as follows:

October 19, just previous to the administration of the drug, it was strongly positive, +++. October 24, strongly positive, +++; November 12, strongly positive, +++; December 6, strongly positive, +++; December 20, strongly positive, +++; Jan. 20, 1911, strongly positive, +++.

Case 2.—*History.*—Varioliform, papulo-pustular syphiloderm. The patient, L. S., a man aged 28, entered the Cook County Hospital, Aug. 23, 1910. The eruption was generalized and typical. The remains of the initial lesion were present. There was general adenopathy. From the date of admission until the administration of the special treatment, hygienic care was exercised. During this time, about two months, the lesions changed their type, becoming entirely papular, but fully as abundant in number as originally. The urinary examination revealed no abnormalities.

Treatment.—October 20, ophthalmologic and general examinations revealed no contra-indications for the treatment. The Wassermann reaction was strongly positive, +++. A dose of 0.5 gm. salvarsan was injected, using the technic as outlined above. This patient suffered sufficient pain to warrant an injection of morphin, gr. ¼, at 9 p. m., five hours after the administration of the salvarsan. Subsequent to this nothing unusual occurred. No indurations remained at the seat of the injection.

Progress and Comments.—After forty-eight hours the lesions were clearing more rapidly than before. Resolution continued for about two weeks, when a recrudescence occurred and during the following three months new lesions kept constantly appearing. The entire number naturally decreased, but the disease was still clinically active. The Wassermann record is as follows: October 24, positive,, ++; November 12, positive, ++; December 20, strongly positive, +++. It is needless to state that more treatment is necessary.

Case 3.—*History.*—Papular syphiloderm. The patient, H. S., man aged 42, entered the County Hospital Sept. 24, 1910. The patient had a fairly generalized, ordinary flat papular syphiloderm, accompanied by general adenopathy.

Examination and Treatment.—October 24, the day of injection with salvarsan, the general examination revealed pulmonary emphysema, but no other complications. The eye-findings were negative. The urinary-findings were negative. The blood-findings showed moderate leukocytosis, 14,050 W. B. C. The Wassermann reaction was positive, +++. Salvarsan, 0.5 gm., was administered. The immediate and later results were not striking. The cutaneous lesions cleared for about two weeks, but recrudescence kept up for the following two months. The Wassermann record is as follows: October 24, strongly positive, +++; November 12, strongly positive, +++.

November 22, the date of departure from the hospital, the disease was still active, though much less so than at the beginning, and more treatment was strongly indicated.

Case 4.—*History.*—Corymbose syphiloderm. The patient, a man aged 35, was admitted to the County Hospital, Sept. 21, 1910. The duration of the eruption at that time was two months; there was a clear history of an initial lesion, and general adenopathy was present. The lesions were generally distributed and typical.

Examination and Treatment.—October 21 a general examination revealed an enlarged liver, but no other findings. The eye-findings were negative; urinary analysis, negative; Wassermann, +++. October 29, 0.5 gm. of salvarsan was administered.

Progress and Comments.—The lesions began to disappear fairly rapidly, but within two weeks new ones occurred, so that the new ones about kept pace with the clearing lesions. New lesions were still appearing, three months after treatment. The Wassermann record is as follows: October 29, strongly positive, +++; November 12, strongly positive, +++; December 6, mildly positive, +; December 20, positive, ++; Jan. 20, 1911, mildly positive, +.

That more treatment must be given is evident.

Case 5.—*History.*—Macular syphilid, ordinary type. The patient, a man aged 23, entered the County Hospital, Sept. 29, 1910. The initial lesion occurred seven weeks previously. A fairly general exanthem, macular type, was present, chiefly on the trunk. General adenopathy was present. This was a typical and ordinary case.

Examination and Treatment.—Just before the administration of the special treatment the urine was found to be normal. The general examination and ophthalmologic examination were both negative as to pathologic findings. October 22, 0.5 gm. salvarsan was administered at 4:30 p. m. At 10 p. m. morphin, ¼ gr., was administered. No local or systemic reaction of moment occurred.

Progress and Comments.—This patient remained in the hospital for three weeks after the treatment. During this period no perceptible change occurred. The exanthem was gradually fading. The Wassermann reaction just previous to the injection was strongly positive, +++. After three weeks, before leaving, it was strongly positive, +++. This patient agreed to return, but failed to do so.

Case 6.—*History.*—Gummatous and ulcerative syphilis. The patient, M. H., a married woman aged 32, entered the County Hospital, Oct. 16, 1910. Three days previously 0.5 gm. of salvarsan had been administered at the clinic in Rush Medical College. The general examination and special examinations had been made there, including a Wassermann reaction, which was positive. This patient was generally weak, had lost weight, was anemic and had two typical deep areas of gummato-ulcerative lesions, one on the forehead involving the frontal bone, and one over the left shoulder.

Progress and Comments.—The nutrition immediately improved. The lesions healed rapidly until the forehead lesion cleared up. The one over the shoulder healed more slowly. The Wassermann reaction remained positive until her departure, five weeks after admittance. In this patient the cutaneous and subcutaneous lesions yielded, but not any more rapidly than they do under ordinary treatment. The nutritive effect was perhaps more marked, but even that is open to question.

CASE 7.—*History.*—Cerebral syphilis and incipient tabes. The patient, a man aged 37 (private patient), was first seen Jan. 12, 1910. The initial lesion occurred in March, 1901, followed by a macular eruption of short duration. During the first year the treatment consisted in the protoiodid of mercury eight weeks at a time, followed by eight weeks of rest during the entire year. In the second year three courses, of four or five weeks' duration each, of the succinimid of mercury, were employed by intramuscular injection. In the third year mixed treatment, including some injections, some potassium iodid, and Bernheim pills, was employed. From then until 1909 a moderate amount of mixed treatment was employed each year. During the second year after infection an incomplete attack of hemiplegia occurred. This involved the left side of the body, but rapidly cleared up. In 1905 a deep ulcer occurred in the tonsillar region, following the removal of this organ for a cervical adenitis. This ulcer healed under mixed treatment. Then for four years no symptoms occurred. In October, 1909, paresis of the external rectus muscle occurred. Energetic treatment with inunctions and potassium iodid made no change in this condition for some time. January 12, when I saw the patient, the above paresis was still present and there were some scorching, intermittent pains in the skin over the left breast. On this date, the findings led to the conclusion that the patient was suffering with cerebral lues, with probably incipient tabes. A Wassermann test at this date was negative (probably influenced by treatment). February 24, pains were noted in both sciatic nerves, also aching pains in both calves; slight unsteadiness in gait, numbness of left ring and little fingers, left cheek and left side of the roof of the mouth; patellar reflexes abolished.

April 24, treatment was suspended on account of saturation. May 9, oculo-motor paresis of the right eye shown by ptosis, dilated pupil and paresis of accommodation of 1 diopter. By May 31 this condition had largely cleared up. June 11 a similar condition arose in the left eye. Treatment during 1910 up to October consisted in injections of salicylate of mercury, potassium iodid and ferruginous tonics. October 28, 0.5 gm. of salvarsan was injected subcutaneously in emulsion.

Examination.—The condition on this date was as follows: Slight Romberg, unsteady gait, patellar reflexes abolished, bladder weak, obstinate constipation, girdle sensation, numbness of soles of feet, left side of face and left hand, intermittent scorching pains in the back; single vision looking straight ahead, but paresis shown by looking to either side, up or down; paresis of both eyes, 1 diopter. Wassermann, positive, +++. Urine, negative.

Progress and Comments.—Following the first injection of salvarsan, great improvement in the general health occurred. The patient gained several pounds in weight in a few weeks; pains all cleared up, gait became steadier, Romberg less marked and bladder stronger; focal symptoms, however, were unchanged. December 15, eye symptoms became exaggerated, and on December 21 a second injection of 0.6 gm. of salvarsan was given in solution into the gluteal muscles, according to the method of Lesser. The Wassermann reaction was still positive. January 27 all symptoms were improving slowly; the Wassermann reaction slightly positive, +.

That the treatment did much for this patient there is no doubt. Much longer observation is necessary to determine the necessary procedure.

CASE 8.—Spinal meningitis (luetic) and tabes. The record of this case is incomplete, but it is included here on account of the fact that of the group this was the only patient who had a systemic reaction.

A general examination of the patient was made before the treatment, and the eyes were examined at the Presbyterian Hospital. December 28 0.5 gm. of salvarsan was injected intramuscularly according to the method of Lesser. On the second day the temperature rose to 103 F., and on the third day to 103.5, and after the fourth day rapidly subsided and the patient left the hospital.

Progress and Comments.—This case is interesting owing to the systemic reaction indicated by the marked elevation of the temperature. There was no nausea; the patient was not particularly ill and apparently recovered rapidly from the attack. His physician reported thirty days after the treatment that the patient was much improved. It was impossible to get another specimen for a Wassermann reaction. This reaction was moderately positive before the original injection.

As will be seen by a study of the above case-reports, marked effect is produced on the disease by this remedy, the most striking in this series being in the case with deep gummatous and ulcerative lesions involving bones and deep structures. The relief of pain, the great increase in the general nutrition of the patient, and the rapid healing of the lesions were striking.

In none of the cases did any untoward results occur. In one only was there any local reaction of any moment and that consisted in an induration which still remains. In three cases an injection of morphin for pain was administered the first night. In none of the others was the pain sufficient to require any sedative. In one case marked elevation of temperature occurred on the second and third days (Case 8). In all of the cases of early syphilis the disease was well advanced and well marked, showing a complete saturation of the patient with the infection. In judging the value of the treatment this fact must be borne in mind.

METHOD OF ADMINISTRATION

The major portion of these patients were injected with the emulsion according to the Wechselmann method. In the last two the solution was injected intramuscularly, according to the method of Lesser. Still later, the instructions were to use the intravenous method. This method does not figure in this experimental report. The latter method is proving more rapidly efficient, but necessarily is attended with more danger, especially as regards general use.

The treatment in the early cases of this group was controlled in a way by other similar cases treated with injections of mercury, and the latter cases apparently made as good progress as those treated with salvarsan and finally better. This, however, does not demonstrate anything essential, except the fact that one injection by emulsion is not sufficient. Had the injections been repeated at intervals of a few days or weeks, as indications demanded, a much different result may have been obtained; and again, the manner of administration may have been less efficient than those now being employed. This group, therefore, seems to demonstrate the inability of a single injection, as here administered, to eradicate the disease.

CONCLUSIONS

This group of cases emphasizes facts demonstrated in the work of a large number of others on record which, summarized, are as follows:

1. Recurrences and recrudescences commonly happen after a single injection, which indicates repeated injections or resort to older methods to complete the eradication of the disease.
2. A marked and profound effect is immediately produced, which makes one indication clear for its use, viz., a rapidly spreading or malignant case in which ulceration threatens vital or useful structures, and an immediate result is imperative.
3. The effect in promoting increased nutrition is marked, especially in cachectic patients, thus placing the patient in a better physical condition normally to combat the invading organisms.

A study of these with other cases demonstrates the facts that salvarsan is a therapeutic agent of great potency; and that it is a valuable addition to our weapons of defense against certain forms of syphilis. The range of these is as yet undetermined. No one can admit that it can, in the present state of our knowledge, replace to any large degree our other well-known and very efficient agents in the treatment of syphilis.

The consensus of opinion now seems to be that it has its greatest usefulness in malignant cases, viz., those in which rapid destruction of tissue is in progress; in mucous membrane lesions about the mouth, tongue, throat, etc.; in the deeper lesions affecting subcutaneous and bony structures, in these the healing of the lesions, the relief of pain, and the promotion of nutrition being remarkable; and finally, in cases (which are fortunately few) which have resisted other well-known measures. Cases in which opinions differ and in which only time will demonstrate the value of salvarsan are the very early cases in which a profound effect on the spirochetes may entirely destroy them before the human organism has become thoroughly saturated, and also the ordinary cases which have in the past been well managed to a successful termination by the usual treatment.

Finally, the greatest credit is due Professor Ehrlich for the production of a chemical remedial agent worked out on scientific principles, and even though it may not ultimately fulfil the unparalleled expectations, it opens a field for research in treatment of parasitic affections that should be of great importance to humanity.

A SIMPLE SUPPORT FOR THIGH ELASTIC STOCKINGS

C. C. JOHNSON, M.D.
CREIGHTON, NEB.

We are sometimes compelled to fit patients with thigh elastic stockings. Several of my patients have complained that they rolled down at the top and became unbearable. The tension produced by fastening the garters to the stockings is so great as to preclude that method of support. I devised this simple method of obviating their trouble. Four or five ordinary dress stays are sewed at varying intervals around the top of the stocking in the longitudinal diameter. It will be found that this ends the trouble. I would, however, suggest that the manufacturers weave small whalebone stays in the stocking in the same manner; this would make a more durable and attractive article.

A CASE OF NEPHROLITHIASIS

WITH REPEATED TEMPORARY RELIEF BY URETERAL CATHETERIZATION

W. P. WILLARD, M.D.
SAN FRANCISCO

The history of this case of nephrolithiasis is, I think, of sufficient interest to be reported.

History.—Mrs. R., aged 41, had been in good health until the birth of her child eighteen years before she came under my observation. At that time she had pneumonia from which she recovered after an illness of two months. Six years later she had ovarian and tubal trouble that necessitated the removal of both tubes and ovaries. Since this operation the patient had never been in very good health. Five years prior to being seen by me the first urinary symptoms appeared, which consisted of painful and frequent urination, and the passage at times of gravel. These symptoms persisted for several weeks and then abated, although the urine continued to be cloudy. Three years later the patient noticed a large, painful swelling in the left side of the abdomen which suddenly disappeared after being present two weeks. At this time a dull pain in the back appeared, and has continued. In January, 1909, she had a severe pain in the right side of the abdomen and back accompanied by a large swelling which disappeared in about ten days.

Examination.—I saw the patient for the first time seven months later and found her suffering greatly with a large, boggy mass extending from the costal border to the brim of the pelvis on the left side. She had a rapid pulse, of high tension, was vomiting and very much prostrated. She had passed no urine for two days and a half, and on introducing a catheter I found the bladder empty. As she was in a very bad condition I advised trying to relieve the condition temporarily by introducing a ureteral catheter.

Treatment.—Some difficulty was experienced in finding the ureteral orifices on account of a chronic cystitis and lack of motion of the openings. On passing a catheter 8 inches into the left ureter an obstruction was encountered. After injecting oil and glycerin with no result, I injected boracic acid solution through a large ureteral catheter, under considerable pressure, and was able to push the catheter to the renal pelvis. The urine spurted from the catheter and within a minute urine could be seen coming from the right ureter. In the first ten hours 1,200 c.c. of urine were passed. The catheter was allowed to remain in the ureter forty-eight hours, and on its removal a mass of mucus and phosphatic sand was passed. After this the patient felt well for six months; then she had a similar attack, which I relieved in the same way. On withdrawing the catheter a calculus 0.5 cm. in diameter was passed. The *x*-ray plates which were made at this time show several calculi in both renal pelves. Operation was positively refused.

Subsequent History.—In March, 1910, the patient again had anuria for thirty-six hours, severe pain on the left side, nausea and vomiting. The obstruction at this time seemed to be at the pelvis; probably one of the stones had engaged in the ureter, blocking the opening. The passage of the catheter had pushed it out of the way and allowed the pelvis to empty. Nothing passed after the removal of the catheter. June 1 the patient again had the same symptoms but was relieved by hot baths and applications. June 29 I was called, after she had tried for twenty-four hours to get relief. Her condition was about the same as described in the first attack, and was relieved in the same way. The obstruction was 10 inches from the bladder. After the catheter had been removed, at the end of twenty-four hours, a calculus 8 by 5 mm. was passed. Between the attacks the urine was full of pus, but the patient was not troubled in any way, except for a dull backache and at times a light night-sweat.

Although this procedure can hardly be recommended for the treatment of nephrolithiasis, still, as a palliative measure in cases in which the condition of the patient makes immediate operation hazardous, and also when small calculi are lodged in the ureter, it is worth trying.

177 Post Street.

Fatigue as a Symptom.—Chronic fatigue is the most obvious symptom in neurasthenia minor. It is true fatigue rather than simple weakness, as is shown by the facts that action is readily excited, but takes an abnormally long time to reach its maximum; that effort cannot be sustained evenly, but shows marked oscillations, and that there is slight incoordination. It is presumably due to the continual production of fatigue toxins. It affects both the mental powers and the physical, probably including the functioning of the viscera.—P. C. C. Smith in the *Practitioner.*

Therapeutics

DRUGS ACTING ON THE CIRCULATION

DIGITALIS

(Continued from page 423)

Therapy.—The conditions improved by this drug are:

1. Poor heart action from any cause except when there is advanced myocarditis, or fatty degeneration.
2. Lack of compensation in valvular disease.
3. Simple dilatation.
4. The irritable or weak heart of nicotin poisoning.
5. The strained heart from over-work or over-athletic exercise, severe marching, mountain climbing, etc.
6. Poor vasomotor tone.
7. Edema or exudations with no serious kidney lesions.

Before discussing the use of digitalis in lack of compensation in valvular disease, it will be well to consider just what is meant by lack of compensation, as this drug should not be used in valvular disease when there is full and complete compensation. Broken or failing compensation means a rapid heart, dyspnea, edema, and passive congestions of the various organs and glands of the body causing disturbed digestion, diminished nutrition, and the retention in the blood of various toxins, the results of mal-metabolism.

This drug does good in *mitral regurgitation* with broken compensation by making the ventricular contraction more complete by directly stimulating the cardiac muscle and increasing its thickness and tone as would result from systematic exercise of any voluntary muscle.

The blood-pressure in the aorta will be increased by the better action of the left ventricle and more blood is thus forced through the coronary arteries, and the nutrition of the heart is improved. Also, the greater contraction of the papillary muscles and the muscle-tissue around the mitral valve makes the opening, due to its incomplete closure, smaller, and less regurgitation takes place.

In *mitral stenosis* with failing compensation digitalis does good not only by strengthening the auricles and the right ventricle which is weakened, but by slowing the heart allows the left auricle to empty itself more completely through the narrowed mitral opening into the left ventricle. In this lesion, with the patient in bed, the heart can be slowed down to about sixty beats a minute with marked advantage. We would here caution that with profound action of digitalis the patient should never rise suddenly from the bed or from a chair, or suddenly rise from bed and evacuate the bladder, as during profound action of digitalis with the heart very slow, such sudden rising and diminution of the abdominal pressure has produced such anemia of the base of the brain as to cause sudden death.

In aortic insufficiency with broken compensation digitalis relieves the symptoms by strengthening the left ventricle, narrowing the aortic orifice, and increasing the lost tone in the aorta and peripheral vessels. Digitalis should not be pushed in this lesion as a prolonged diastole from much slowing of the heart would be of great disadvantage, and a pulse above eighty in this lesion is better than a slower pulse.

Some clinicians believe that digitalis should never be used in aortic insufficiency. However, if not used to profound effect it will often do a great deal of good when compensation has been broken in this condition. The main strain on the heart in this lesion is in the left ventricle, and the left ventricle is the part of the heart most helped by digitalis. Increased blood-pressure is not desirable in aortic insufficiency, and but slight increase in blood-pressure will occur if the digitalis is administered in small doses, though the heart muscle will be stimulated to better contraction. It is dangerous to slow a heart with aortic insufficiency below seventy, and it certainly is dangerous to slow it to sixty, as the prolonged diastole not only prevents more blood being sent upward through the carotids and cerebral arteries, but also, during diastole blood is flowing backward from the aorta into the left ventricle. At the same time, the blood is flowing toward the right auricle through the superior vena cava and therefore also from the jugular veins. The result of a prolonged diastole is anemia of the base of the brain, and this is one of the causes of sudden death in aortic regurgitation. Another danger of prolonged diastole in this lesion is of an over-filling of the left ventricle with regurgitated blood and a consequent paralysis. If serious dropsy occurs from aortic insufficiency the condition is much more serious than in mitral disease, and the prognosis is bad.

When there is lack of compensation in *aortic stenosis* digitalis will improve the condition by strengthening the left ventricle, thus overcoming the resistance at the aortic orifice. However, this drug should not be pushed in this condition, as a too sturdy action of the left ventricle against the resistance will weaken the muscle wall. In this lesion this drug often acts best when administered conjointly with nitroglycerin to keep down the peripheral resistance.

It is understood, of course, that nitroglycerin administered at the time the digitalis is administered is of no avail in counteracting any action on the blood-vessels of that particular dose of digitalis, but if digitalis is administered twice in twenty-four hours and nitroglycerin four times or more in twenty-four hours, more or less continuance of lowered blood-pressure will occur. It may be stated here that although in the laboratory the effect of lowering of the blood-pressure of a single dose of nitroglycerin lasts but a short time, clinically it is a positive fact repeatedly noted that in conditions of high blood-pressure when nitroglycerin in proper dose is administered, even not more than four times in twenty-four hours, the average blood-pressure is continually lower than without this drug.

The satisfactory action of digitalis when compensation is weakened in valvular disease may be many times repeated, but sooner or later in valvular lesions with recurring incompetency the cardiac muscle becomes so deteriorated that digitalis no longer is able to restore the hypertrophy. Some patients do well with small doses of digitalis long continued, for months and even years. Other patients with valvular disease and incompetency, after the hypertrophy has been restored by digitalis, may not again need a cardiac drug for months until some unusual exercise, or mental anxiety, or severe sickness has again broken the compensation, and again digitalis will improve the condition. Rarely, however, in patients who have repeatedly taken digitalis, or in some few patients always, some other cardiac medication will act better than does digitalis.

In any condition in which the *right side of the heart* alone is dilated and incompetent without valvular lesions, as occurs in pulmonary disturbances such as pleurisy, empyema, advanced tuberculosis, and especially emphysema, digitalis is of benefit. This is true in spite of the denial by some experimenters that digitalis acts at all on the right ventricle.

In conditions of sudden *cardiac failure or shock* from any cause the action of digitalis is so slow, even if given hypodermatically, that it should not be relied on to meet the emergency. If the shock or cardiac distress can be overcome for the time being by other drugs, digitalis given at the time will in some hours begin to add its powerful stimulation to the heart and blood-vessels.

In *simple hypertrophy* of the heart, or when the compensation is complete in valvular lesion, digitalis should *not* be used.

In the various stages of *acute endocarditis* occurring as a complication in acute rheumatism it is hard to decide whether digitalis should, or should not, be used. On the one hand the heart at this time should not be stimulated to more sturdy contraction. On the other hand, the slowing of the heart can but do good by modifying the movements of an inflamed organ. If the heart with endocarditis is beating at the rate of 110 beats a minute, it would seem good treatment to cause such physiologic rest as would be produced by reducing the pulse-rate to eighty or ninety beats a minute.

Probably early in endocardial inflammation local application of ice is the best method of slowing the heart. Next, if the conditions allow it, perhaps small doses of aconite may be administered for a day or two; later, nitroglycerin may act well to slow and quiet the heart. After the acute symptoms are over it cannot be decided offhand that small doses of digitalis will not aid a heart in its repair. Most clinicians believe digitalis should never be used in this condition. Some experimental proof has seemed to show that small doses may tend to produce a more complete recovery of the heart. If a second attack of endocarditis is superimposed on a previously damaged heart and both together cause broken compensation sufficient to produce edemas, the problem whether or not digitalis should be given is still more difficult to solve.

In *pericarditis* this drug will help the laboring heart.

In the feeble heart of chronic *myocarditis* and of *fatty degeneration* the utility of digitalis is much less pronounced, and the advisability of using the drug at all has been much questioned. However, in many of these cases if the drug is given cautiously and in small doses it will prove of considerable benefit, as in many cases we are not certain that there is actual degeneration of the cardiac muscle; and also it is impossible to decide how extensive the degeneration is even if we assume that it actually exists. It is plain that we should not deny the patient the possible benefit from digitalis though at the same time the action of the drug should be carefully watched. Degeneration of the cardiac muscle is frequently due to inadequate nutrition caused by impaired circulation through the coronary arteries. The orifices of these arteries are covered by the semilunar valves during the systole of the heart; consequently, these arteries are not supplied with blood during its active propulsion through the aorta. But during the diastole when the aortic valve is closed the elastic rebound of the blood in the aorta fills these arteries and gives to the heart its nutrition. If the aorta is imperfectly filled, or if the blood is allowed to flow back into the left ventricle on account of the imperfect closure of the semilunar valves, or if the blood-pressure is abnormally low, the coronary arteries will not receive an adequate amount of blood and the nutrition of the heart will be impaired, and degeneration of the cardiac muscle will take place. When any of these conditions exist, digitalis, by throwing a large amount of blood into the aorta, by causing more complete closure of the semilunar valves, and by increasing the blood-tension in the arteries, will cause an increased amount of blood to enter the coronary circulation, and the nutrition of the heart improves. Hence, digitalis will delay the progress of the degenerative process unless there is serious atheroma of the coronary arteries, but it cannot, of course, restore structures already degenerated. This latter fact makes the use of digitalis so often disappointing in the condition of chronic myocarditis. If acute myocarditis is diagnosed or surmised, digitalis should not be used.

When there is *irregularity* of the heart without any valvular lesions or signs of cardiac insufficiency, occasionally digitalis will improve the rhythm. This is especially true when the heart misses an occasional beat from previous over-exertion or cardiac strain. Under these conditions digitalis often relieves the cardiac discomfort and renders the pulse regular. If there is cardiac pain at the same time there is irregularity, digitalis will often increase that pain and do harm. In most instances of this malfunction strophanthus acts better than digitalis. If there is arteriosclerosis, nitroglycerin will improve the condition.

Not infrequently when there is complete *heart block*, digitalis should be used with caution, although of course it is possible that a better ventricular contraction and an improved aortic blood-pressure may cause more perfect circulation and therefore better nutrition to the part of the heart that is in trouble in this condition.

Digitalis should not be used in *endarteritis* or in atheroma, and hence, ordinarily, not in *aneurysm*. If aneurysm occurs early in life when the arteries are not diseased, in certain selected cases it might be used with care if it were otherwise indicated.

In *cerebral inflammations*, or in any acute cerebral condition, digitalis is contra-indicated, but in the insomnia of *neurasthenics* or when there is general *vasomotor debility*, when the patient is drowsy when up and awake, and wakeful when he lies down, the tone of the blood-vessels being so poor that they dilate in the lower part of the body when the patient is up and in the head when he lies down, digitalis oftentimes acts as a good soporific. Digitalis may be used for this purpose alone, or if given conjointly with more active hypnotics will make a much smaller dose of the hypnotic successful than when it is used without the digitalis. In fact, in neurasthenic conditions or in conditions of vasomotor debility digitalis is a general tonic for the whole system, improving the general circulation and increasing the general nutrition. Profuse sweating, especially in the axillæ, in neurasthenic patients is improved by digitalis.

In *delirium tremens*, whatever cardiac treatment is given should be given hypodermatically, as drugs given by the stomach are either not absorbed at all, or are absorbed very slowly, which accounts for the harmlessness of the enormous doses of digitalis given by the mouth in this condition.

In *chronic alcoholism* before hardening of the arteries has occurred this drug is undoubtedly of advantage.

Digitalis has been recommended and used for various *internal hemorrhages*, especially for hemoptysis, but it is a question of doubt whether a drug which raises the blood-pressure as does digitalis is rational treatment. The success which has attended its use in this condition is probably really the coincidence of the natural cessation of the hemorrhage. Venous hemorrhages, either from the nostrils or from the lungs, are often stopped by the administration of digitalis. This is especially true if there are valvular lesions. Ordinarily, however, it must be remembered that drugs that raise the blood-pressure are not indicated in internal hemorrhage. In other words, such drugs as digitalis, ergot, strychnin, and atropin are generally contra-indicated. Those that lower the blood-pressure, as the nitrites, are the drugs that should be used.

On account of the slowness of its action, digitalis is not indicated in *shock* and *collapse*. Also, it has been shown by experimental evidence that animals in condition of shock do not live as long when treated with digitalis as those who are not so treated. Therefore, it is inadvisable to use digitalis in this condition.

In *purpura* and in hemorrhagic diathesis, digitalis, by contracting the blood-vessels, may tend to diminish the frequency of the hemorrhages. There are other treatments, however, more useful.

This drug by contracting the blood-vessels of the genital organs has been thought to act as an *anaphrodisiac*, and it has also been used in *spermatorrhea*. In these conditions, when there are local causative irritations and inflammations, digitalis would be of no benefit. If there were a general vasomotor debility digitalis could be good treatment.

Though not a very well-established fact, it is considered by some writers that digitalis will stimulate the uterus to contract, and hence this drug has been used in menorrhagia. It could do good only as a general circulatory tonic. It has also been recommended in *post-partum hemorrhage*, but any action in this condition would come too late to be of value, and as the bleeding is from the open veins, it is difficult to understand how it could do any good except by later improving the lost tone of the systemic vessels.

In *edema* from other causes than valvular disease, as occurs in anemia, especially of the lower extremities, when combined with other proper treatment digitalis is of marked benefit. *Chronic eczema* and ulcers of the leg, with or without varicose veins, are often benefited by digitalis.

When there are *effusions* without kidney lesions, or when there is chronic liver disease digitalis is often of benefit.

In *Graves' thyroid disease* this drug given for a long time may do considerable good by overcoming the dilated condition of the blood-vessels caused by the hypersecretion of the thyroid. Its power of slowing the heart, however, in this condition is very limited, and large doses to produce that result would probably not be justified though its prolonged use might gradually aid in establishing a cure.

The use of digitalis in *renal disease* is much discussed, some clinicians advising it and others denouncing it. No fixed rule can be given. In acute congestion of the kidney, digitalis should not be used. The same is theoretically true in uremic poisoning. However, with low vasomotor tension and a weak heart digitalis should be tried in not too large doses. If it does not give good results in thirty-six or at most forty-eight hours it should be stopped. If the results are good, the size of the dose should be diminished as over-action from digitalis can certainly readily take place in kidney lesions.

In the diseases of the lungs above cited with a strained right side of the heart, this drug is of advantage. It is also useful in many cases of *chronic bronchitis*, aiding the recovery by improving the pulmonary circulation. Small doses are also often of benefit in severe *whooping-cough* in which the right side of the heart is subjected to such serious strain.

Digitalis has been used in *pneumonia*. Whether it is of advantage in this disease can be decided only by the individual case. Not every pneumonia patient should receive digitalis, but the condition of the heart may call for it. In the first stage it should not be used; in the second stage it may be used; in the third stage, especially where there is slow resolution, in combination with other appropriate treatment it may often be of marked advantage. If there is "prune juice" expectoration, showing a venous stasis, or insufficiency of the right ventricle, digitalis may be advisable at any stage of pneumonia. A few clinicians use digitalis throughout the pneumonic process, but they have not satisfactorily proved their case, and digitalis has seemed at times to increase the pulmonary congestion, increase the dyspnea, and cause dangerous symptoms.

Often during pneumonia the urine shows albumin and the kidneys secrete an insufficient amount of urine, even without any apparent cardiac failure. During pneumonia, digitalis, instead of increasing the urine output, frequently seems to decrease it, and the cumulative effect of the drug during this disease is readily caused.

Some clinicians advise the use of digitalis *as an antipyretic*. Before we can accept an antipyretic action of this drug in non-poisonous doses, we must know what other treatment was given in the cases in which the antipyretic action took place. The action of high internal temperature on the pneumogastric nerve or its center in the medulla is such that many times digitalis will not slow the heart, hence it should not be pushed in fevers, if it is given at all. Also, when there has been prolonged fever the cardiac muscle becomes weakened and perhaps slightly degenerated, and we here have another reason for giving digitalis in very small doses, as it is not justifiable to add much irritation to an injured organ.

Contra-Indications.—High tension of the arteries, atheromatous conditions, weak cardiac muscle from prolonged fevers, from fatty degeneration, or from myocarditis, and ordinarily serious kidney lesions should contra-indicate the use of digitalis. Inflammation of the stomach should cause some other cardiac drug to be substituted.

Digitalis is useless, if not harmful, in an attack of tachycardia and in a failing heart after a severe fever, and should not be used in these conditions. It cannot be relied on to do any more than aid the circulation when there are large effusions.

Official Preparations.—The following are the official preparations:

Digitalis: The dried leaves, dose 0.05 gram (about 1 grain).

Extractum Digitalis: Average dose 0.03 gram (½ grain).

Fluidextractum Digitalis: Average dose 2 drops.

Infusum Digitalis: Average dose 10 c.c. (about 2 fluidrams) or 2 teaspoonfuls.

Tinctura Digitalis: Average dose 10 drops.

Non-Official Preparations. — Various supposedly assayed watery and alcoholic extracts of digitalis are on the market, and some tinctures are prepared in such a manner as to have the fatty part of the digitalis removed. Such tinctures seem to be less likely to cause irritation of the stomach, and are therefore better tolerated. Even in these supposedly assayed preparations the strength at times varies, and the dose of any one single preparation of digitalis is *enough* to accomplish the object desired, unless undesirable symptoms occur which prohibit further use of the drug.

Digitalinum: Digitalin is a varying product as it occurs in the shops and may or may not represent a desired activity. It is a white or yellowish white powder, odorless and bitter. Until this product is absolutely pure and always the same the beginning dose should not be more than 1/25 of a grain. However, a dose as high as ¼ of a grain may be given before the physiologic effect of the drug desired is obtained. It must be remembered, however, that even this glucosid administered hypodermatically acts very slowly.

Digitoxin: A good preparation of *digitoxin* on the market is under the name of "digalen." Investigation of this product has seemed to show that it is a digitoxin perhaps not so strong as the pure crystallin digitoxin. Digitoxin represents an active principle of digitalis, and acts a little more quickly than other principles, and is eliminated a little more quickly, but does not represent the whole value of digitalis as represented by a fresh infusion of good leaves or a properly made fluidextract or tincture. Some experimentation has seemed to show that digitoxin is more likely to raise the blood-pressure undesirably and therefore precipitate a cumulative effect by its action on the kidney vessels, while, if its action is satisfactory, it will be more rapidly eliminated than some other of the digitalis glucosids. This means that a digitoxin preparation, with the kidneys healthy, is less likely to cause a cumulative action when the drug is long continued than is the whole drug. On the other hand, with the kidneys deficient, it is perhaps more liable to cause cumulative action than is the whole drug.

Digitoxin is now used with considerable frequency in therapeutics. It is insoluble in water and is irritant, and therefore should not be used hypodermatically. It seems to decompose rather rapidly, and probably therefore loses its efficiency. While it frequently steadies an irregular heart better than the whole drug, its tendency to contract the blood-vessels more than the whole drug should preclude its use when high blood-pressure or arteriosclerosis are present.

Administration.—The best preparations for internal administration are the infusion, freshly prepared, and the tincture. These preparations would be incompatible only with such drugs as are incompatible with all infusions and tinctures of vegetable drugs. If the other official preparations are used, the digitalis leaves should be given in powder or capsule, the extract in pill or capsule, and the fluidextract alone. The drug is not expensive and perhaps not often adulterated, but if the infusion is ordered one should be sure that it is made from the fresh leaves and not from the fluidextract. The infusion is no better preparation (except possibly as representing an extract of good leaves) than is the tincture, if the tincture is a good one. The dose of the infusion is always given so much larger relatively than the dose of the tincture, that the infusion gets the credit for more efficient work. The tincture is only about six times stronger than the infusion; therefore, the equivalent dose of the infusion to 1 c.c. (15 minims) of the tincture is 6 c.c. (1½ fluidrams).

"Digipuratum" is an extract of digitalis leaves representing the active principle. It is offered in powder and in tablet form. It is insoluble in cold water and acids; but easily soluble in dilute alkaline solutions. Each tablet contains 0.1 gm., and one a day, or less, is supposed to be sufficient, if to be given for any length of time.

Digitalin is probably the preparation of digitalis most used hypodermatically, and as previously stated, it has been urged that it is used in too small doses, which is the reason so little effect has been produced. However, the French expect to get results from 0.001 gram (1/60 of a grain) of digitalin, and some French clinicians advise this dose given once, and then no more for three weeks, combined with rest in bed, purgation, and a milk diet; this for cardiac dropsy.

It is certain that the satisfactory action of digitalis is evidenced by diuresis which, however, is not in positive evidence until from thirty-six to forty-eight hours after the first dose. Some clinicians, notably the French, as just stated, seem to think that one large dose of digitalis, whatever the preparation be, is more efficient in its results, when there is cardiac insufficiency with edema, than smaller doses. Smaller doses are used when there is simple palpitation and dyspnea without edemas. Very small doses are given when it seems advisable to give the drug for a long period. In fact, the more one reads of the recommendations of various writers as to the use of digitalis, the more confused one becomes. The following seem to be valuable suggestions as to the dosage of digitalis:

1. It must be known that the preparation used is a good one.
2. No immediate symptoms of the action of digitalis must be expected. It cannot exert its physiolgic action until at least twelve hours, and not its full activity for at least from twenty-four to thirty-six hours.
3. If there are conditions present that present a doubt as to whether digitalis will do good or harm, the dose should be medium or even small and given three or four times in twenty-four hours, and if ascertained that the action is for good, the frequency of the dose may then be diminished.
4. If positive indications for the need of digitalis action are present without conditions of doubt being present, as arteriosclerosis or myocarditis or fatty heart, a large efficient dose should be given at once and then no more for from thirty-six to forty-eight hours.
5. Digitalis should not be used in shock or in cardiac failure in acute disease.

Mine Rescue Cars.—Why the deaths in American mines during the year 1909 should be about 5 out of every 1,000 employed, and in European countries only about 2 out of every 1,000, has caused inquiry. It has been found that this great difference is due largely to the fact that for some years past certain European countries have maintained efficient rescue stations. M. M. Hunting (*Scientific American*, Jan. 7, 1911) describes the six mine rescue cars equipped by the Bureau of Mines for rescue work. These cars are equipped with the latest apparatus including first-aid materials and are manned with experienced miners drawn for this work. They are stationed at the great coal mining centers, one in Wyoming, one in Montana, one at Salt Lake City, one in Illinois, one in Tennessee and one in Pittsburg, Pa. A surgeon from the American Red Cross Society and a mining engineer are members of the crew of each car. They will visit all mining towns of importance in their allotted territory and deliver lectures and give demonstrations on the use of explosives, electric apparatus, fire prevention, sanitation, etc. Rescue brigades will be formed at each place and each car will contain eight oxygen helmets and a supply of oxygen in tanks, twelve safety lamps, a field telephone and wire, outfits for resuscitating asphyxiated miners, etc. Men at each place will be trained in the use of the oxygen helmets, which permit the miner to enter the mine immediately after an explosion while it is full of poisonous gases. Such an equipment would no doubt have saved many lives in recent mine disasters.

POSTANESTHETIC INFECTIONS

Modern surgery has rendered the occurrence of serious infections of operation wounds a rarity, but it has not succeeded so well in abolishing postoperative infection of the lungs. The development of pneumonia after an operation, even though the greatest care be taken in both anesthesia and operation, is always a dreaded possibility, and one which no amount of precaution can positively eliminate. In well-conducted surgical clinics the mortality from postoperative lung infections undoubtedly exceeds the mortality from infections arising in the operation wounds; the latter are reduced by careful technic to practically zero, while the lung complications, although much reduced by improved methods of anesthesia and better care of the patient during and after the operation, still remain a serious menace.

The reasons for these lung infections are obvious enough. Direct irritation of the respiratory passages by the anesthetic vapors, chilling of the tissues by the ether-cooled air, to say nothing of aspiration of saliva and food materials through the ineffective larynx during deep unconsciousness, are adequate to account for pneumonia. Our newly acquired knowledge of the part played by the blood in preventing and controlling infection also shows us that there is more than a local pre- osition to infection, for after anesthesia the power e blood to destroy pathogenic bacteria is markedly ced. In fact, the members of the entire group of ol, ether and chloroform reduce the power of the d to combat bacteria; the state of a man after a long thesia is comparable to that of an alcoholic with bronchitis who has been sleeping off an overdose of alcohol in a doorway or a freight-car.

So important a subject is this postoperative pneumonia that much interest attaches to the recent studies of Graham[1] on anesthesia and the bactericidal powers of the blood. According to these experiments, it is not the power which serum itself has of destroying bacteria through bacteriolysis which is reduced by anesthetics, but the destruction of bacteria by phagocytosis is greatly reduced. Now it so happens that the organisms which we have to fear in surgery, the pneumococcus and the pus cocci, are destroyed chiefly through phagocytosis and not by bacteriolysis, which gives added importance to this depressing effect on the bactericidal powers of the blood. Apparently ether, the anesthetic which Graham has studied, reduces both the efficiency of the opsonins and the power of the leukocytes to take up the sensitized bacteria; these effects can be seen both in the blood of patients or animals after anesthesia, and in drawn normal blood treated with ether in the test-tube. The action of the ether is not permanent, the opsonic power being restored promptly on removal of the ether.

As the distribution and action of ether in the living body is closely dependent on its great solubility in fats and lipoids, Graham sought to learn if these substances might not influence this undesirable inhibitory action of ether on the bactericidal properties of the blood, with suggestive results. Lecithin, when added to etherized serum, was found to restore the opsonic power to normal, and—what is of especial practical importance—the subcutaneous injection of lecithin into animals, immediately after anesthetizing them, was found to cause the opsonic index to rise much more rapidly than it did in control animals. This effect of lecithin apparently depending chiefly if not entirely on its ability to take up ether from aqueous solution, the action of olive oil was then tried and found to be similar. The application of this principle to clinical uses was then made by giving rectal injections of olive oil to patients immediately after anesthesia, with a strikingly rapid return to normal of the opsonic power of the patient's blood as the result. So simple and logical a procedure as this is entitled to a general and thorough trial, which it will undoubtedly receive, especially in view of its assured harmlessness. In estimating its results, however, it must be borne in mind that the lowered bactericidal power of the blood is only one of the conditions which favor the development of postoperative pneumonia; the local injury to the lungs will still exist as a source of danger, and we can scarcely expect to eliminate entirely all possibility of pneumonia, no matter how promptly we may be able to restore the phagocytic activity of the blood.

THE DIMINISHING BIRTH-RATE

Everywhere a cry of alarm goes up at the diminishing birth-rate. The biologist deplores the apparent decrease in the virility and fecundity of the species; the publicist shudders at the possibility of the extinction or decreased importance of the nation.

The subject of the birth-rate, increasing or diminishing, is one which always seems to arouse agitation; it is one, moreover, about which opinion has oscillated for more than a hundred years. About half a century ago, John Stuart Mill, coolest and least emotional of thinkers, wrote apprehensively of Great Britain as "a country overpeopled or threatened with being so." In the eighteenth century, on the other hand, learned writers, with equal pessimism, maintained that the population of the known world had declined since the palmy days of the great nations of antiquity; and grave fears were entertained, even as they are to-day, lest the tendency might continue indefinitely.

---

It was at this juncture that Malthus came forward with his theory of the necessary limitation placed on the numbers of population by the means of subsistence. The best population, he taught, was not necessarily the largest, any more than it was the smallest; it was the population which was best nourished, most industrious and most moral. Increase in numbers was good so far, and only so far, as was consistent with maintenance of the quality of population.

It is interesting to note the swing of the pendulum once more toward the position of Malthus. For instance, two recent writers attempt to show, the one, that the cause of the diminishing birth-rate is, in the main, the prudence and not the degenerated physique of individuals; the other, that it is a necessary factor in the advance of civilization among nations.

Professor Emerick[1] concedes that the stress of modern life and the involuntary sterility induced by venereal diseases may be contributing factors in the declining birth-rate, but he insists that this does not offer a satisfactory explanation of the phenomenon. Though it may be admitted, as some authorities hold, that venereal diseases are responsible for fully 25 per cent. of inability to procreate in men and for more than 50 per cent. of enforced sterility in women, to say nothing of one-child sterility, this, Emerick thinks, leaves us quite in the dark as to the real proportion of involuntary sterility. He believes that there is little evidence that incapacity due to sexual diseases has become more common, and that it is not clear that venereal diseases are most common in that portion of the population in which the birth-rate is lowest. He also believes that the fall in the birth-rate has been too sudden and marked to be accounted for by the energy expenditure demanded by modern life. Nor do the modern sedentary occupations, the higher education of women, and the other more or less artificial conditions of life operate to reduce the birth-rate without the volition of the individual. According to Malthus, the birth-rate is less among barbarous than among civilized races, and in civilization the birth-rate has fallen among laborers and mechanics as well as among brain-workers; among the inhabitants of rural communities, as well as among those of the cities. In the evolution of the race nothing has become more firmly fixed than the power of reproduction. The persistence of the procreative power is one of its most marked characteristics. This is notorious among many kinds of degenerates.

The most potent reasons, then, in Emerick's view, for the limitation of the birth-rate are found in the personal preference of the individual, and in economic compulsion. He says that the increased expense of producing self-supporting men in this day limits their supply as truly as expense limits the production of commodities. Moreover, the economic reason that once rendered marriage compulsory for women has now lost much of its force, or even acts in the opposite way. The will of the woman has consequently become more influential, not only in determining the formation of the family, but in the admission of new members to it. Of course these reasons involve many others, such as postponement of marriage, desire for ease, aims and ambitions inconsistent with marriage and offspring, etc. Emerick's conclusion is that the diminishing birth-rate is primarily volitional, and that the various factors which make for involuntary sterility are of minor importance.

Taking the larger view of the question, as applied to nations rather than to individuals, Dr. Nearing[2] undertakes to prove the converse of Emerick's proposition, namely, that the restriction of population is economically a problem of survival. In 1800 the population of the United States, for instance, was doubling itself, by natural increase, to say nothing of immigration, every twenty-five years. Had that rate of increase continued, in 1900 the native-born population would have numbered about one hundred million, and in 2,000 A. D., it would have increased to eight hundred million. In the United States in 1910, with considerably less than one hundred millions of people, already the alarm has been raised that our land has all been taken up and much of its fertility has been exhausted, so that we are being warned against the danger of insufficient food to supply our rapidly increasing population, while the increased cost of that which is available has become a serious public problem.

Formerly wars, pestilence and famine served to keep down the population; but modern science and the spread of intelligence have increased the average length of life and reduced the death-rate so radically—say to sixteen per thousand—that the figures of the calculation quoted do not correspond to the population of 1900, disregarding the elements we are discussing which have intervened to keep the population down to a possible subsistence basis.

In other words, we come back to the position of Malthus: Population is inevitably limited by the means of subsistence. Given a certain subsistence available at a given place and a given period, capable of supporting a certain number of well-rounded lives, if the total number of lives exceeds the given optimum, the lives of some or all must be curtailed in length or breadth or in both. Beyond a certain point, a rise in the birth-rate entails a rise in the death-rate and a fall in the average standard of living.

[2] Nearing, S.: "Race Suicide" vs. Overpopulation, Pop. Sc. Monthly, January, 1911, p. 81.

It would be rash to attempt to find in these essays any basis for finality on the subject. A survey of the fluctuations of opinion, however, offers the comforting suggestion that we may well postpone our panic fears of depopulation and overpopulation until statistical science and the collection of statistics have made a little more progress and are able to inform us with certainty which we really need to fear.

BLACKWATER FEVER AND MALARIA

Although it is generally accepted that blackwater fever—the acute febrile hemoglobinuria of tropical and subtropical regions—is malarial in origin, no means has as yet been found to demonstrate this with certainty; and not infrequently there appear enthusiastic advocates for its specific character. Such a one is Craig,[1] who, in an able review, presents a strong case against the malarial hypothesis. This hypothesis is founded on the following evidence: first, the occurrence of the disease only in malarial districts, and its greatest frequency in localities infested with pernicious malaria; second, the presence of plasmodia in the blood either just before or during the attack; third, the fact that most, if not all, sufferers give a history of previous malarial attacks, and ordinarily have spent a long period in a malaria-infested region; and last, the fact that the blood-picture, a relative increase in large mononuclear cells, is that of malaria. But Craig points out that, although blackwater fever occurs only in malarial districts, many such regions, and even such as are infested with the severe type of the disease, are quite free from cases of the hemoglobinuric affection. As instances of this he cites Italy, where blackwater fever is rare, while the neighboring islands of Sicily and Sardinia suffer severely from it. In India it is restricted to certain limited areas of the malarial regions; in the Philippines, where pernicious malaria is of great prevalence, blackwater fever is almost unknown. Further, instances of house infection are recorded, in which all the cases occurring in a certain neighborhood came from one or two dwellings only. Another significant fact is that the disease appears to be spreading. Thus it is only in late years that the west coast of Africa has suffered from it and in India, too, it has been reported only comparatively recently. Yet both of these regions have been sites of pernicious malaria from time immemorial. That neither previous malarial infection nor long residence in malarial localities is required to produce the disease, is shown fairly conclusively by the citation of numerous cases in which one or the other factor was absent, or both. And the same applies to the occurrence of plasmodia, since instances are recorded in which careful blood-examinations before and during the attack, and even splenic puncture, have failed to reveal them. In regard to the significance of the blood-picture, the same findings occur in other tropical protozoan infections, as sleeping-sickness and kala-azar. As to the quinin theory of the cause of blackwater fever, many cases have been reported in which quinin had not been administered to the sufferer. Craig also affirms that the giving of quinin has no effect on the course, but the general consensus of opinion and statistical evidence do not seem to support him on this point. The evidence for specificity consists in part of the facts already presented. Further, the occurrence of several well-established epidemics speaks strongly in its favor. Finally, the pathology, while not distinctive, differs enough from that of malaria to bear some weight.

Brem,[2] writing still more recently, is inclined to the view that by "blackwater fever, we in reality describe two distinct affections." The one he considers a manifestation of excessive erythrocytic destruction by malarial parasites, and therefore a type of pernicious malaria. This he designates as "pernicious malaria with hemoglobinuria." The other, with less striking evidence of plasmodial infection, he describes as "erythrolytic hemoglobinuria." As to the etiology of this second form, he offers no suggestions, beyond stating that, in some cases, at least, quinin apparently acts as a direct exciting cause. His statistics, as well as others quoted by him, appear to bear out the contention that quinin has a deleterious action in this form.

Finally, the whole subject is complicated by a recent discovery by Urriola,[3] who states that all cases of malaria, however latent, show masses of blood-pigment in the urinary sediment, similar to that announced long ago by Laveran as present in the blood-stream, but not hitherto considered of diagnostic importance. It would appear, however, that the urinary pigment, although of hemic origin, is enough modified to remove it from the scope of hemoglobinuria, since Brem failed to get hemoglobin tests in the urine of numerous mild and moderate cases of malaria.

The whole problem is one that presents unusual obstacles. The difficulty of deciding absolutely as to the occurrence of malaria in any given case is alone enough to delay its solution. And without careful animal experimentation—to the necessity for which Craig calls attention—it is improbable that any absolute decision can be attained.

ANCIENT PROBLEMS OF PHARMACY, AND THEIR WARNING

Most physicians of modern times would be quite sure, if they thought about the matter at all, that the pharmaceutic problems which prove so troublesome in our time represent abuses that have crept into medicine because of peculiar developments in the last few generations. Certainly very few would think that these problems—proprietary remedies and their abuse, substitution, counterfeiting of drugs, the use of long, imposing Greek names to make new compounds popular and impressive—were all features of a previous phase of medical history. In this matter the story of medicine at Rome during the early empire is particularly interesting. Social and economic conditions were not very different from ours; indeed, as the Italian historian Ferrero made very clear in his American lectures, they were in many ways remarkably like those of our day and country. If we bear this in mind, it is not so surprising to find that our problems in pharmacy resemble theirs so closely as to be almost a perfect replica. The value of history consists largely in the applicability of its lessons to the aftertime; unless we can see the fitness of the application, it becomes scarcely more than a tale that is told. The history of pharmacy, therefore, at Rome, has its special interest at this time.

[2] Arch. Int. Med., 1911, vii, 153.

[3] Semaine méd., 1911, xxxi, 3.

Pliny the elder, for instance, complains that physicians of his time (the first century after Christ) often bought their remedies already prepared so as to avoid the trouble of preparation. He evidently refers to compounds of various kinds supposed to be curative for various affections; for Friedländer[1] says that "often the physicians did not know the exact ingredients of the compounds that they used and should they desire to make up written prescriptions, would be cheated by the salesmen." Both Galen and Pliny complain of the fact that physicians used "ready-made" medicines instead of original prescriptions carefully prepared by or under the supervision of the physicians themselves. It is evident that the proprietary remedy had come into existence thus early, and that various drug manufacturers had made specialties which physicians, following the line of least resistance, found it easy to prescribe, though men like Pliny and Galen realized very clearly that this was an abdication of one of the most important functions of their profession, which was bound to work harm in the end both to themselves and to their patients.

Galen has much to say with regard to the frauds practiced on physicians by the "cursed dealers," as he calls them, who substituted one drug for another whenever they found it difficult to fill a prescription as it had been ordered. He admits that not infrequently the drug-compounders were themselves the innocent victims of "collectors of herbs who brought saps and flowers and fruits and sprouts into towns" and of others who compounded remedies of various kinds for sale to the pharmacies. He confesses that the ingenious methods of counterfeiting practiced by some of these men would deceive any but the experts. Galen himself, in his younger years, had been a pupil under a man who "forged balsam, Lemnian earth, white flowers of zinc and other rare drugs to perfection and succeeded in making a great deal of money by this means.[1]" Galen even insisted rather emphatically that an imported article was not necessarily genuine or pure, quite as in our day he would probably have proclaimed that being "made in Germany" was not in itself an assurance of scientific or ethical quality. He himself preferred to obtain his drugs from the proper regions and through reliable dealers and friends on whose absolute honesty he could depend. This whole picture of the drug trade in imperial Rome, as Friedländer gives it in a page or two, would read almost like an antedated satire on certain conditions of our time; but it is sober history.

Other details seem even more strangely familiar to physicians of the present time. For instance, many remedies were known by special arbitrary names instead of descriptive names recalling the ingredients. Sometimes they were named after famous physicians who had used the remedies in question or were said to have done so; again, the preparations were named for persons of distinction who actually or supposedly were cured thereby, much as, in our own day, cigars are named for poets, statesmen and actors. The titles of some of these preparations for instance, were "Ointment for Gout, made for Patroculus, Imperial Freedman—Safe Cure"; "Ointment for Aburnius Valens" (probably the famous jurist) called the "expensive ointment"; "Eye Salve used by Florus on Antonia the wife of Drusus [the Emperor's son] after the other doctors had nearly blinded her." Many of these remedies were labeled "instantaneous," "safe," "sure cure." "harmless remedy," and the like. Frequently euphonious names, sometimes from the Greek, were chosen for these remedies—Ambrosia, Anicetum, Nectarium, and the like. The promoters evidently knew the satisfying effect on both physician and patient of a long, mystifying foreign name. George Eliot says that we map out our ignorance in long Greek names; but certainly the pharmaceutic equivalent of "that blessed word Mesopotamia" seldom fails to produce a wonderful feeling of assurance and of confidence in the therapeutic potentialities corresponding to its majestic syllables.

The source of these abuses was just the same in Rome nineteen centuries ago as it is here to-day—greed for money. To use Friedländer's words, "Wealth was the genius of the noisy, restless striving which daily filled the streets and palaces; one universal chase after money as the original good, whence were derived rank, respect and honor. The complaint was just that wealth was the sole criterion and the one aim of Rome." From this universal money-seeking came the approximate commercialization of the professions; hence the abuses that flourished in pharmacy and in medicine. The lesson is complete. The protests of Pliny and of Galen were impressive, but Rome was deteriorating; there was no professional organization to check these abuses, and they increased as Rome declined. Evidently if we are to avoid such unfortunate deterioration in our own time, we must not shrink from recognizing and resisting the evils which do so easily beset commercialized ages like those of the first and the twentieth centuries A. D.

Current Comment

MADAME CURIE AND THE ACADEMY OF SCIENCES

The recent candidacy of Mme. Curie for the vacant seat of M. Gernez in the Académie des sciences of France has aroused much interest outside of that country, and the news of her defeat will doubtless be a disappointment to many who seldom feel any concern about the distribution of foreign academic honors. Justly or unjustly, public opinion outside of France will incline to interpret the result of the election as a discrimination, on grounds of sex, against a scientific investigator of high standing. The academy, however, has avoided the responsibility of officially excluding women. As explained by our Paris correspondent in this issue, the agitating question of feminine candidacy was laid before the Institut de France, of which the Académie des sciences is a component part. The institute passed a resolution advising respect for "immutable tradition," but declining to interfere with the autonomy of the five affiliated academies. The Académie des sciences presented Mme. Curie as a candidate, thereby tacitly admitting the principle of the eligibility of women. On the first ballot Mme. Curie received but one vote less than her successful rival. To what degree her defeat is to be attributed to the undoubtedly strong feeling against the admission of women cannot be judged from this distance. Her successful competitor is, we are assured, a member who confers honor on the illustrious body to which he has been elected; and it would doubtless be unfair to ascribe his election chiefly to prejudice against a woman candidate. The narrowness of the margin by which Mme. Curie was defeated suggests that a similar contest might some time have a different ending. The election of so distinguished a woman as Mme. Curie to the Académie des sciences, if that should ever occur, would certainly add to rather than detract from the honor conferred on other members, since it would indicate that no personal consideration outweighed scientific attainments in the selection of members.

VINDICATING THE TUBERCULIN TEST

The report of the milk committee of the Illinois legislature, which was adverse to the tuberculin test, on the ground that a positive reaction is not a reliable indication of tuberculosis in cattle, received a severe body-blow in a test recently made in Chicago. The action of the committee was followed by the introduction into the legislature of a bill (House Bill 55), which seeks to prohibit the enforcement of the tuberculin test by municipalities. This was introduced in the interest of those milk-producers of the state who assert that the test is not conclusive. This assertion has been disputed vigorously by the Chicago health authorities, who have been enforcing this test in the dairies which supply milk to the city of Chicago. The milk-producers, confident of their ability to show the fallacy of the tuberculin test, sent to the Chicago stockyards fourteen cattle that had been found tuberculous by the tuberculin reaction. The cattle were killed and after examination by the state and federal inspectors all were condemned as being seriously infected with tuberculosis. Two cows which had not reacted were found free from tuberculosis. According to the newspapers, tuberculin tests of cows furnishing milk for the Kansas City market show that nearly fifty per cent. are infected, and so many were condemned as temporarily to curtail the milk-supply going to that market. The cattle owners there are likewise protesting against the condemnation of their cattle. Following the Chicago demonstration of the accuracy of the tuberculin reaction in cattle furnished by the opponents of the test, the Illinois legislature should carefully consider this feature of the bill referred to before making it a law. Large numbers of similar demonstrations in this country have shown the relative accuracy of the test. There can be no question of the value of the tuberculin test of cattle, and the passage of a law by the Illinois legislature prohibiting this test and substituting, as proposed, the ordinary clinical tests, would be a distinctly backward step, one not in the interest of the health of the people of the state. The milk-producers of Illinois and adjoining states have an association primarily to further legislation of this character in their own interests, and at a recent meeting, plans were laid for the formation of a national association. Hence the question is likely to become broader than one affecting a single state.

PHARMACEUTICAL JOURNALS AND THE NOSTRUM

We had something to say elsewhere[1] as to the attitude of the pharmaceutical profession and pharmaceutical journals concerning the advertisement and sale of nostrums. Attention was called to two journals which had adopted a policy of consistency, and which were supporting THE JOURNAL's propaganda against the nostrum evil. It appears from recent utterances against certain widely advertised nostrums that the *Pacific Pharmacist* of San Francisco belongs also in the ranks of those journals which regard professionalism as higher than the good will and patronage of "patent medicine" fakers. In the December (1910) issue—commendably clean in its advertising pages—the *Pacific Pharmacist* continues the publication, under the head of "Propaganda for Drug Reform," of a list of nostrums condemned by the Department of Agriculture under the Food and Drugs Act, and calls "particular attention to cancer and headache fakes." In an editorial on vicious advertising, in the same issue, the *Pharmacist* says: "We cannot think of any good reason why our daily papers should be permitted to continue their vicious advertising." Reference is made to a number of that class of advertisements appearing in a San Francisco daily paper, and the opinion is expressed that such advertising should be made a criminal offense. In the same issue, also, a correspondent, commenting on the work of the Council on Pharmacy and Chemistry of the American Medical Association, says that pharmacists "are in sympathy with those who are trying to eliminate drugless drugs and with those who are endeavoring to make drugs of value to be of standard quality," and that "the representative physicians of the United States recognize in the pharmacists a spirit of cooperation and the ability to assist them in this noble enterprise." Evidently the leaven is working, and ere long other pharmaceutical journals will get in line, and, together with their three pioneer contemporaries, will be able to render most valuable assistance in cleaning up the nostrum business, as it affects both the public on the one hand and the medical and pharmaceutical professions on the other.

GLUTEN FLOUR

In previous issues attention has been called to many so-called gluten flours and their supposed value in the dietary of diabetics. The misconception as to the value of the gluten content, rather than the absence of the carbohydrate element, on which their value really depends in diabetes, was emphasized. It was further pointed out that the regulations concerning the percentage of gluten and of carbohydrates and the branding of such products under the Food and Drugs Act are unsatisfactory and tend to be misleading. In this issue is an abstract of the discussions on the subject of gluten flour at the Second International Congress for the Repression of Frauds. This is a purely commercial body, and its discussions are interesting as showing the attitude of the various members—manufacturers, bakers, pharmacists, physicians—on this subject. The physicians insisted that in making a definition for gluten flour or bread it was just as important, or more important, to state the maximal permissible quantity of carbohydrates as it was to state the permissible minimum of gluten. The definition finally adopted was much more satisfactory than the requirements of our Food and Drugs act, in that it provides that "only breads containing a maximum of 25 per cent. of wheat starch and a minimum of 60 per cent. gluten, calculated on the basis of dry material, shall be called gluten bread." While 25 per cent. is a dangerously high proportion of carbohydrate for a diabetic food, yet it is much safer than many of the so-called diabetic breads and flours at present on the American market. A maximum of 10 per cent. of carbohydrates for all flours or foods advertised for diabetics would, as a legal requirement, do much to protect the sufferers from this disease and would work no hardship on the manufacturer. Further than that, all such products should be plainly labeled so as to show the actual percentage of carbohydrate content. When this is done one of the most disgraceful and dangerous of the many frauds perpetrated by American food manufacturers will have been eliminated.

SANATORIUM TREATMENT OF TUBERCULOSIS

An interesting and encouraging indication of the possibilities of the sanatorium treatment of tuberculosis in the climate of Illinois is afforded by the report of the Edward Sanatorium at Naperville, which we recently summarized in our News Department.[1] In an illustrated pamphlet, the medical director, Dr. T. B. Sachs, reviews what has been accomplished in the four years since the founding of the institution, which consists of a farm of forty acres and the equipment. The latter has been developed until it now comprises a medical building with laboratories, an infirmary, an assembly room, a service hall, open-air shacks, tents, etc., for the accommodation of sixty patients. Modern hygienic and dietetic methods of treatment are in force, two objects being kept in view: the arrest of the tuberculous process, and the restoration of the earning power of the patients. Originally independent, the sanatorium is now conducted under the auspices of the Chicago Tuberculosis Institute. To January, 1911, over 400 patients had passed through the sanatorium, the average stay of each being about four months, and in the report 277 cases are analyzed. The results reported are surprisingly favorable. Of 176 patients in the incipient stage 161 or 91.5 per cent. at the beginning of 1911 were in apparently normal health, with full working capacity, at periods of from six months to three years and nine months since their discharge. In addition, 5.1 per cent. possessed partial working capacity. Of ninety-one moderately advanced cases, 32 patients or 35.1 per cent. had full working capacity, while 16.5 per cent. had partial working capacity. On admission, each patient is studied thoroughly by all the methods of physical diagnosis and the laboratory. Absolute rest is enforced until any constitutional disturbance subsides and nutrition improves; then exercise is gradually introduced, and later graded work becomes a feature. The work is individualized and made agreeable. Recreation and amusement are provided and most of the time of the patient is spent out of doors. The report shows that, even in a climate which seems inimical to the best results in the outdoor treatment of tuberculosis, under a proper study of cases and a proper régime, carefully and intelligently carried out, an excellent showing can be made anywhere in the treatment of tuberculosis, as has also been demonstrated in the Adirondacks and elsewhere. One important effect of such sanatorium treatment is that the patients discharged have received such an education in right living that their influence after returning to their families and friends must be most salutary.

Medical News

ILLINOIS

Auxiliary Staff at County Hospital.—To facilitate the performance of emergency operations at Cook County Hospital, the Civil Service Commission has appointed six physicians to assist the regular attending staff. The new positions of chief of staff, night surgeon, and medical statistician have been created at the hospital.

Personal.—Dr. Joseph P. Pecival, formerly superintendent of the State Hospital for the Insane, Norfolk, Neb., has been appointed superintendent of the Cook County Institutions, Dunning.——Drs. John A. Graham, George N. Pratt and Hugh N. MacKechnie, Chicago, have been appointed as the voluntary attending medical staff in the Oak Forest Infirmary. One of the new appointees is to visit the institution each day.——The damage suit instituted against Dr. John W. Daugherty, Chillicothe, in which $20,000 was claimed by the plaintiff on account of alleged malpractice, came to an abrupt ending, January 17, as the plaintiff failed to make her case.

Another Suit Against Illinois Board.—It is reported that the Littlejohn College and Hospital, formerly known as the

---

[1] The Journal, Jan. 14, 1911, p. 126.

American College of Osteopathic Medicine and Surgery, has begun mandamus proceedings against the Illinois State Board of Health to secure recognition of that college by the board. The charge is that the board is unlawfully discriminating against that college. The suit filed for a similar purpose by the National Medical University in December, 1909, is still pending but that college is still unrecognized.

Bills Introduced in Legislature.—Two bills providing for a board of examiners in optometry have been introduced in the General Assembly, namely Senate Bill 140, by Mr. Brown, and House Bill 121, by Mr. Hagan. During last week the following bills were introduced: Senate Bill 155, by Mr. Hurburgh, to appropriate $100,000 a year for the College of Medicine of the University of Illinois; House Bill 149, by Mr. Chipperfield, to establish a state surgical institution for children under 14 years; and House Bill 152, by Mr. Perkins, to amend the pure food act.

Chicago

Women Physicians Reorganize.—At a meeting, held in the Fine Arts Building, February 1, by fifty women physicians of Chicago, it was voted to reorganize the Chicago Medical Women's Club. It is intended to launch an educational campaign in which milk, food and health problems will be publicly discussed.

A Saner Fourth.—At a meeting of the Sane Fourth Association, held February 8, it was decided to have a great celebration in Grant Park, and in addition to utilize every small park and public playground. It is intended that each nationality shall participate in the general and special celebrations, that folk songs and dances shall be made special features in certain localities.

Personal.—Dr. Alice Hamilton of the Memorial Institute for Infections Diseases, who investigated the lead industries in Chicago and Illinois, with reference to lead poisoning, for the Illinois Commission on Occupational Diseases, has undertaken similar work for the federal government.——A prospectus received announces that, after nearly twenty years of labor on an English translation of the "Papyrus Ebers," Dr. Carl H. Von Klein (who may be addressed in care of the John Crerar Library, Chicago) has completed the task and will publish a subscription edition.

KENTUCKY

Medical Society Election.—At the meeting of the Jessamine County Medical Society, held in Nicholasville, Dr. Thomas R. Welch was elected president; Dr. Daniel A. P. Lenick, vice-president, and Dr. J. A. Van Arsdall, secretary-treasurer, all of Nicholasville.

Appropriation for Babies' Milk Fund.—As the result of the plea of Mrs. Litchworth Smith, president of the Babies' Milk Fund Association, made in an address before the fiscal court of Jefferson County, the sum of $1,500 was unanimously voted for the benefit of the association toward its expenses this year.

Moving Pictures for the Insane.—Arrangements have been made by the new state board of control of charitable institutions to install a moving-picture machine at the Central Kentucky Asylum for the Insane, Lakeland. By the contract, patients are to be given two shows a week with six new films at each performance.

Expense Falls on Hospital Commission.—It is announced that the expense attached to the temporary housing of patients, during the construction of the new Louisville City Hospital, must be borne by the Hospital Commission alone. The section in the law which created the Hospital Commission makes it optional with the city whether or not it shall bear the whole or part of the expense attached to the temporary housing of the City Hospital patients.

MARYLAND

Honor System Adopted.—The students of the Medical Department of the University of Maryland have adopted the honor system and have drawn up a code of laws for carrying it out.

Personal.—Dr. James J. Murphy has succeeded Dr. George Wells as chief of the medical staff of Annapolis Emergency Hospital.——Dr. Richard C. Massenburg is reported to be ill with bronchitis at his home in Towson.

Dispensary Report.—At the annual meeting of the Northeastern Dispensary, Baltimore, Dr. Arthur Wegefarth was elected president, and Dr. Alexander D. McConachie, secretary. During the year nearly 20,000 patients were treated at the dispensary; 23,332 prescriptions were filled, and 1,074 visits were made to patients' homes.

New Hospital Buildings.—A stone hospital is to be built at St. Mary's Industrial School near Baltimore to cost about $25,000.——An additional hospital building to accommodate 200 patients is to be erected at the Maryland Tuberculosis Sanatorium. It will contain also quarters for physicians, nurses and help, offices, kitchen and living room.

Health Conference.—At the health conference held in Osler Hall, February 6-11, under the auspices of the Medical and Chirurgical Faculty of Maryland, Dr. William H. Welch presided. Among the many important addresses presented were those by Dr. Woods Hutchinson, New York City, on "How the Public Educates the Medical Profession;" Dr. Henry H. Goddard, Vineland, N. J., on "The Feeble-Minded Child as a Menace to Society, Socially and Morally;" Dr. Lyman F. Kebler, Washington, D. C., on "Advertised Cures for Tuberculosis;" Dr. F. Park Lewis, Buffalo, on "Good Sight as a National Asset;" Dr. Cressy L. Wilbur, on "Unrecorded Babies;" Dr. Llewellys F. Barker, Baltimore, on "Prevention of Nervousness in Children and the Protection of the Nervous Child," and Dr. Ronald Godfrey Freeman, New York City, on "The Relation of Good Milk to Infant Mortality."

MASSACHUSETTS

Alumni Meeting.—The annual meeting of the Boston City Hospital Alumni Association was held February 15. In the morning there were demonstrations of cases in the hospital, followed by a luncheon in the library.

Association of Boards of Health Meets.—The Massachusetts Association of Boards of Health, held its annual meeting, January 26, and elected the following officers: president, Dr. Henry P. Walcott, Cambridge; vice-presidents, Drs. Samuel H. Durgin, Boston, and Charles V. Chapin, Providence, R. I.; secretary, James C. Coffey, and treasurer, James B. Field.

Personal.—Dr. Dwight S. Woodworth has been appointed a member of the board of health of Fitchburg.——The following appointments have been made to the medical staff of the Tuberculosis Commission of Lawrence: chief of staff, Dr. Charles G. Carleton; ophthalmologists, Drs. William H. Merrill and Frank A. Conlon, and medical staff, Drs. John J. Bartley, J. Forrest Burnham, John J. O'Sullivan, Harry H. Nevers, John H. Tobin, Victor A. Reed, George B. Sargent and Granville S. Allen.

Medical Council Meeting.—At the annual meeting of the Council of the Massachusetts Medical Society, Dr. David L. Edsall, St. Louis, formerly of Philadelphia, was appointed the Shattuck Lecturer at the annual meeting of the society in June, 1911. The following delegates were elected to American Medical Association: Dr. Frederick H. Thompson, Fitchburg; Frank G. Wheatley, North Abington, and Hugh Cabot, Boston; alternates, Drs. Isaac S. F. Dodd, Pittsfield; Allen Greenwood, Waltham, and Fred T. Murphy, Boston; Maine Medical Association: Drs. George K. Blair, Salem, and Herbert W. Manahan, Lawrence; New Hampshire Medical Society: Dr. George Z. Goodell, Salem, and Omer P. Porter, Lowell; Rhode Island Medical Society: Drs. Allen Greenwood, Waltham, and Nathaniel S. Hunting, Quincy; Connecticut State Medical Society: Drs. Everett A. Bates, Springfield, and Samuel B. Woodward, Worcester; council on medical education of the American Medical Association: Dr. Harold C. Ernst, Boston, and alternate, Dr. Horace D. Arnold, Boston; auditor, Dr. Chauncey C. Sheldon, Lynn, and member of committee on publication to succeed Dr. John C. Munro, deceased, Dr. Edward W. Taylor, Boston. It was voted to pay the mileage of delegates to meetings of the American Medical Association, and to instruct delegates to make reports to the council after the meeting. It was also voted that on the first annual meeting of the society each section should elect its officers for the coming year. It was voted that the revised list of medical schools and colleges in the United States and Canada be the standard on which future fellowship in the Massachusetts Medical Society be based.

MICHIGAN

Clinic at Harper Hospital.—The medical staff of Harper Hospital, Detroit, will give medical, surgical and laboratory clinics at the institution, February 24 and 25 from 8 a. m. to 5 p. m. The medical profession is invited to be present. It is the aim of the staff to hold several of these clinics each year. The program includes medical and surgical clinics and practical laboratory work. No charges or fees are made for these clinics.

Personal.—Dr. John V. Frazier, Lapeer, has been appointed a member of the Board of Control of the State Home for the Feeble-Minded in that city.——Dr. Clark E. Spencer, Port Huron, is reported to be seriously ill at his home.——Dr. Don D. Knapp has been appointed health officer of Flint, vice Dr. Myron A. Patterson, resigned.——Dr. John H. Kellogg, Battle Creek, has been appointed a member of the State Board of Health, vice Dr. Angus McLean, Detroit, and Dr. Thomas M. Koon, Grand Rapids, has succeeded Dr. Malcolm C. Sinclair, Grand Rapids, as a member of the board.

MISSOURI

Decide Site for Children's Hospital.—The Hospital and Health Board of Kansas City have decided to erect the new children's hospital on the southeast corner of the new general hospital grounds.

Committee on Public Health.—Dr. Jefferson D. Griffith, Kansas City, president of the Jackson County Medical Society, has appointed the following committee on public health and registration: Dr. Franklin E. Murphy, Andrew W. McAlester and Rush E. Castelaw. One member of this committee, will, it is expected, meet with the mayor at the executive committee meeting of the city council each Monday morning.

Personal.—A fire at Denver, February 4, totally destroyed the office of Dr. Calvin F. Forbis.——Dr. and Mrs. Benjamin Belove, Kansas City, have returned after two years abroad. ——Dr. James R. Hull has sold his interest in the Monroe Hospital, Monroe City, to Dr. John N. Southern.——Dr. Jesse E. Hunt, school inspector of Kansas City, has resigned.—— Dr. John M. Doyle, St. Joseph, physician of Buchanan County, has resigned and has been succeeded by Dr. James K. Graham, St. Joseph.——Dr. William C. West, Kansas City, while making a professional call, was attacked by a negro, whom he put under arrest. He was stabbed twice in the breast but not seriously injured.

St. Louis

Changes at St. Louis University.—At the St. Louis University School of Medicine, Dr. Charles Hugh Neilson, formerly professor of physiologic chemistry, has been advanced to the chair of medicine which has been placed on a salary basis. It is planned to have other clinical chairs likewise placed on a salaried basis so that the appointees may devote their entire time to the work in their departments.

Acquitted of Failure to Report Disease.—Dr. John H. Kern, charged with having failed to report a case of chicken-pox to the board of health, and fined $25 in the police court, was discharged by Judge Miller in the court of criminal correction. Judge Miller, in his decision, says in effect that a physician is not a scout or detective, and it is not his business to go into homes and ascertain the existence of a contagious disease, even though he may suspect that such disease exists.

Personal.—Dr. Henry Hanson, Webster Groves, has been appointed physician of St. Louis County.——Dr. Charles H. Dixon, who has been seriously ill in Cleveland, is reported out of danger.——Dr. Amand N. Ravold, medical director of the Missouri State Life Insurance Company, has resigned.——Dr. George Buckner is reported to be seriously ill with septicemia. ——Washington University announced, February 10, the appointment of Dr. Fred T. Murphy, Boston, as professor of surgery in its medical department.

NEW YORK

Personal.—Dr. Anna M. Stuart has been appointed city bacteriologist of Elmira.——At the meeting of the Elmira Academy of Medicine, February 1, Dr. Arthur K. Bennett, who recently returned after ten years missionary service in Persia, read a paper on vesical calculus, with special reference to conditions found in Persia.

Newell in Rochester.—At the meeting of the Section of Obstetrics, Gynecology and Pediatrics of the Rochester Academy of Medicine, February 15, Dr. Franklin S. Newell, Boston, delivered the address of the evening on "The Requirements of Modern Obstetrics." A dinner was given in honor of Dr. Newell prior to the meeting.

Macdonald Memorial.—An association has been formed for the purpose of raising funds for a memorial for Dr. Willis G. Macdonald, and Governor Dix has been named president. A meeting was held in Albany, on February 3, where plans were discussed for raising the sum of $100,000. The memorial will probably take the form of a laboratory for Albany Medical College.

Probing State Hospitals.—The stewards of the various state hospitals held a conference at Utica on January 21, with a representative of the auditing committee which is engaged in investigating the affairs of the state hospitals. A searching investigation is being made and recommendations were made as to improvements in methods and system of accounts and caring for supplies and property.

Plan for Milk Commission.—As a result of the disclosures in connection with the milk business, especially in New York City, a bill has been introduced into the legislature by Assemblyman Foley, which provides for the appointment of a milk commission to have general supervision over the milk dealers in the state and over persons buying and selling milk in cities of the first class, the commission to consist of three persons appointed by the governor at an annual salary of $5,000 and the principal office to be in New York City. The measure provides that the commission shall have the power to investigate the quality and price of milk and to fix standards of quality. The bill carries an appropriation of $5,000.

Lecture on Public Health.—Monroe County Medical Society plans to give Rochester the benefit of a series of free lectures on preventive medicine and public health. The series will consist of eight lectures given on alternate Friday nights during February, March and April. The first lecture was given by Dr. F. Park Lewis, Buffalo, February 3, on "Conservation of Vision." The subsequent lectures are on "Occupational Diseases and Their Prevention," by Dr. Eugene H. Porter, state health commissioner; "Deformities and Their Prevention," Dr. Wisner R. Townsend, New York City; "Cancer and Its Cause and Prevention," by Drs. William S. Bainbridge, New York City, and Harvey R. Gaylord, Buffalo, and "Prevention of Insanity," which will be given in cooperation with the State Charities Aid Association.

New York City

Lying-In Hospital Alumni Meet.—At the meeting of the Alumni Association of the Lying-In Hospital of the City of New York, held at the Harvard Club, February 14, the paper of the evening was read by Dr. John O. Polak, Brooklyn, on "What Can We Expect From the Vaccine Treatment of Puerperal Sepsis."

Personal.—At the eighteenth annual dinner of the Long Island Medical Society, held in Brooklyn, February 7, the guest of honor was Dr. John O. Polak, one of the oldest members of the association.——Dr. William S. Bellows, Jamaica, who has been traveling in search of health for the last five months, has returned home.

Crusade Against Spitters.—Health Commissioner Lederle has announced that 160 persons have been arrested since January 1 in the crusade against the spitting nuisance. Of sixty persons arrested during the first week in February, forty were fined and in sixteen sentence was suspended. Only fourteen out of the 160 have been discharged outright.

Annual Report of Dispensary.—Dr. Alfred H. Riedel, house physician and registrar of the North-Western Dispensary, reports that this is the only institution in the city of New York which furnishes everything absolutely free to its applicants. During 1910 the total number of patients treated in the clinics was 17,538; the total number of visits made to patients at their homes was 9,178.

Medical Lecture Series.—The Educational Alliance has planned a series of lectures on medical topics to be given during February, March and April at Alliance Hall. The first lecture will be given by Dr. William M. Polk, president of the Academy of Medicine, on February 23, on "Medical Ethics and Their Application to Practice;" the second on March 30, on "Gynecologic Operations by the General Practitioner," by a lecturer to be announced later, and a third on April 23, by Dr. J. Brettauer on the "Secret Division of Fees."

Infantile Paralysis.—Health Commissioner Lederle has announced that since the Health Department, on November 1 last ordered that physicians report all cases of infantile paralysis as a communicable disease, eighteen cases have come to the attention of the Health Department. The division of communicable diseases has been giving special attention to this affection. Inspectors have been instructed to be very careful and exact in obtaining information as to periods of incubation and infectivity, since negative may be as important as positive findings.

Medical Society Secures Appeal.—A new trial was ordered in the appelate division of the supreme court, February 3, in favor of the New York County Medical Society, which appealed from a judgment of $7,500 obtained against it by Paul Schmitt, charged with practicing medicine without legal authority. The court, in its opinion, stated that at the trial the evidence established in substance that the real plaintiff was not authorized to practice; that he held himself out as Dr. Schmitt and claimed that he could cure glanders; that an article appeared in a newspaper to the effect that a Dr. Gannett was in Bellevue Hospital suffering from glanders, and that this article was shown to the plaintiff by one Conrad, who, at the time, said he had written to Dr. Gannett, the letter being signed "The Department of Glanderine, per C. Conradus, Secretary," offering to cure him free of charge.

Approves Directory.—At a meeting of the Medical Society of the County of New York, January 23, a preamble and resolutions were adopted setting forth that a communication had been received from the Medical Society of the County of Chemung, advocating the discontinuance of the Tri-State Medical Directory, similar communications having been sent to other county medical societies in the state; recording the disapproval of the Medical Society of the County of New York of any effort to discontinue the directory; instructing its delegates to the state society to oppose strenuously any effort to discontinue the directory, and directing that a copy of the resolutions and the reasons therefor be sent to the secretaries of the county medical societies of the state, and the officers and members of the house of delegates. These reasons are that the directory is of supreme importance to the physicians of the cities which furnish the overwhelming majority of the membership of the state society; that the abolition of the directory would cause a loss of membership; that the employment of the directory is reciprocal between city and country practitioners; that the directory has proved to be a most efficient collector, as members are anxious to appear in good standing; that the directory is regarded as authoritative by boards of health, life insurance companies and other business concerns; that the directory is the most potent weapon against quackery; that the directory is an absolute necessity to larger medical societies; that the expense charged to the directory may be misleading in some particulars, and is counterbalanced in some measure by the income from advertising and sales; and that the directory is one of the most important material benefits in building up a powerful organization of medical societies.

NORTH CAROLINA

Personal.—Wake Forest College has secured Dr. W. T. Carstarphen for the chair of physiology in the department of medicine.——Dr. Franklin W. Griffith has located in Asheville.

Hookworm in Asheville.—Dr. Claude L. Pridgeon, one of the Hookworm Laboratory workers, reports, as the result of the examination of scholars in Asheville City graded school, that from 25 to 40 per cent. are infected with the hookworm.

Society Meetings.—At the annual meeting and banquet of the Buncombe County Medical Society, held in Asheville, the following officers were elected: president, Dr. Clyde E. Cotton, Black Mountain; vice-president, Dr. Charles L. Minor, Asheville; secretary-treasurer, Dr. Gaillard S. Tennent, Asheville, and Drs. S. Westray Battle, Marshall H. Fletcher and Carl V. Reynolds, all of Asheville, delegates to the State Medical Society.——Wake County Medical Society at its annual meeting held in Raleigh, January 12, elected Dr. J. A. J. Penny, Roger's Store, president; Dr. Joel Whitaker, Raleigh, vice-president; Dr. William C. Horton, secretary, and Dr. Kemp P. Battle, Jr., treasurer.

OHIO

Personal.—Dr. George W. Crile has succeeded Dr. Dudley P. Allen as chief of the visiting and surgical staff of Lakeside Hospital, Cleveland.——Dr. Andrew J. Timberman, Columbus, has returned after a trip to India.——Dr. Charles O. Probst, secretary of the State Board of Health, Columbus, is reported to be ill with influenza.——Dr. Solomon B. Hiner, Lima, is reported to be seriously ill with pneumonia.——Dr. Jacob J. Coons, Columbus, has been appointed pathologist of the State Board of Health.——Dr. Oscar H. Sellenings has succeeded Dr. Jacob A. Stout as president of the Columbus Board of Health.

Elections.—At the annual meeting of the Cleveland Medical Library Association, the following officers were elected: president, Dr. Charles B. Parker; vice-president, Dr. Benjamin L. Milliken, and secretary, Dr. Henry L. Sanford. It was announced that the sum of $150 has been offered by a friend of the library for a prize for the best medical paper on any subject in medicine and surgery to be submitted to a committee of judges before September 1, the competition to be open only to members of the library who have graduated within the last ten years.——At the annual meeting of the Lakeside Hospital Alumni Association, held January 18, the annual address was delivered by Dr. Alexander Primrose, Toronto. Dr. Henry L. Sanford was elected president; Dr. Arthur H. Bill, vice-president, and Dr. Gilchrist, secretary-treasurer.

Cincinnati

New Board of Health Official.—The Cincinnati Board of Health, at a recent meeting, established the position of kitchen inspector, the position to be filled by a woman at a salary of $600 a year.

Report of Antituberculosis League.—The financial report of the Cincinnati Antituberculosis League shows total receipts of $22,777.96, and disbursements of $6,017.68. Dr. Otto P. Geier was elected president; Dr. Samuel Iglauer, secretary, and Drs. Samuel E. Allen, John M. Withrow, Edwin W. Mitchell, Albert Faller, H. Kennon Dunham and William H. Strietman, trustees.

PENNSYLVANIA

Officers Elected.—At the organization of the Allegheny Valley Branch of the Allegheny County Medical Society, the following officers were elected: President, Dr. Adam C. Davis, Hites; vice-president Dr. William F. Ross, New Kensington; clerk, Dr. Nannie M. Latimer, Tarentum; and treasurer, Dr. Thomas E. McConnell, Parnassus.

The Afflicted.—While Dr. David H. Bemis, West Middletown, was making a professional call, his horse slipped and fell on him, fracturing his right leg.——Dr. Edward G. Husler, Carnegie, is in the West Penn. Hospital, Pittsburg, suffering from cerebral hemorrhage.——Dr. Wilmer R. Batt, Harrisburg, is reported to be convalescent after an operation for appendicitis.

State to Adjust Hospital Appropriations.—In order to adjust state appropriations to hospitals, the house appropriation committee has obtained a report showing the number of free days of treatment given by each hospital of the state in the last two years and Governor Tener and legislative leaders are agreed that state money shall go largely to hospitals giving most public benefit.

State Aid for Charity.—The preliminary report of the Board of Commissioners of Public Charities suggests that steps be taken for the examination of the several systems of children's aid as now dispensed, with the view to the establishment of a uniform system on a more substantial and exalted plane. The amount asked by Philadelphia institutions was $4,772,000, and the amount recommended for distribution by the board was $2,252,000.

Personal.—Dr. Samuel G. Dixon, Harrisburg, has been reappointed state health commissioner.——Dr. Ira J. Dunn, Erie, has returned after six months abroad.——Dr. James F. Edwards, superintendent of infectious diseases, has resigned the chairmanship of the Pittsburg Tuberculosis Commission.——Dr. George R. Vernon, president of the Clifton Heights Board of Health, has resigned.——Dr. John Todd has been reelected president of the Pottstown board of health for the eighteenth consecutive term.

Philadelphia

Addition to Hospital Opened.—The children's building of the Samaritan Hospital was opened January 19. The new building is erected to the memory of the late James L. Miles, and is the latest annex of the hospital. It contains, in addition to the children's ward, a large number of private rooms.

Statue for College of Physicians.—A heroic-sized statue of the Greek physician, Æsculapius, cut in a beautiful block of Carrara marble by the Roman sculptor, Maneti, will be presented to the College of Physicians at its next meeting. The statue is a gift of Dr. Richard H. Harte, a member of the college, and was originally intended to occupy a niche at the first landing of the marble staircase, but it is thought that it may have to be erected elsewhere, owing to its great size and weight.

Census of Defective Children.—The census of defective children in the public schools of the city is now complete and shows that there are 11,543 mentally deficient pupils. Three kinds of deficiencies are considered in the report: First, the physically deficient, embracing the blind, deaf, speech defectives, crippled and epileptics; second, the mentally deficient, backward, feeble-minded and imbecile and third, the morally deficient, truants and incorrigibles. The first class, backward children who require instruction by special methods in small special classes, number 1,857 boys and 1,063 girls; and dull children, who would be benefited by special instruction, 3,362 boys and 3,241 girls; class 2, feeble-minded children who should properly be in custodial institutions, 287 boys and 165 girls; girls 3, truant, incorrigible and vicious children of defective mentality, who should be segregated in special schools, 387 boys and 607 girls; truant, incorrigible and vicious children of fair mentality who should be segregated in special schools, 1,082 boys and 40 girls.

Personal.—Dr. S. Weir Mitchell has been renominated as a member of the board of managers of the University Museum. ——Dr. George W. Merscher, chief resident physician of the Germantown Hospital, was operated on in that institution, February 7, for appendicitis.——Dr. Joseph Walsh has returned from a three months' tour of Egypt and the Orient. ——Dr. Owen Copp, Brookline, Mass., for twelve years head of the Massachusetts State Board of Insanity, has been appointed physician-in-chief and superintendent of the Pennsylvania Hospital for the Insane, known as Kirkbride's.——Drs. Charles K. Mills and William G. Spiller have been elected foreign corresponding members of the Paris Society of Neurology.——Dr. Charles Furbush, chairman of the milk Commission, has been appointed by Mayor Reyburn to represent Philadelphia at the International Exhibition on Hygiene, to be held in Dresden in May.——Dr. Edward A. Spitzka, professor of general anatomy in the Jefferson Medical College, is recovering from a serious attack of blood poisoning. ——Dr. Jesse O. Arnold has been elected president of the Samaritan Hospital Medical Club.——Dr. J. William White has been made a trustee of the University of Pennsylvania; Dr. John B. Deaver, clinical professor of surgery, and Dr. Milton B. Hartzell, professor of dermatology.

Children's Hospital Plans Completed.—The architects have completed plans for the group of buildings to be erected at Eighteenth, Fitzwater and Bainbridge Streets, for the Children's Hospital, the cost of which, when completed, will be $500,000. The group will consist of an administration building, dispensary, nurses' home and ward building in the Georgian style of architecture, fire-proof and set well within its own grounds and surrounded by an open iron fence. The site measures 308x203 ft., includes half a block and was donated by Eckley B. Coxe, Jr., one of the board of managers, who gave $100,000 for the purpose. Several houses have since been purchased for space for a power plant, laundry, etc. The buildings will conform to the latest ideas in hospital construction; covered passageways join the various buildings, forming elevated walks free from dampness; wards light and airy, three roof gardens for convalescents and thorough screening for the exclusion of flies.——Mrs. Anne McMichael Hoyt has conveyed to the Children's Hospital the residence at the southeast corner of Twenty-Second and Chancellor Streets, with a stable in the rear. These properties were presented to the hospital, which they adjoin, as a memorial to her deceased father, Morton McMichael. This gift greatly enhances the value of the present hospital, the sale of which will give fully half the money required for the new buildings.

Society Notes.—At the annual meeting of the Philadelphia Neurological Society, January 27, the following officers were elected: president, Dr. Alfred R. Allen; vice-presidents, Drs. John H. W. Rhein, and Samuel D. Ingham; secretary, Dr. George E. Price; treasurer, Dr. S. DeWitt Ludlum; and councilors, Drs. James H. Lloyd, H. H. Donaldson, and Francis X. Dercum.——The physicians and druggists of the northern section of the city have organized the Northern Medical League for the purpose of furthering the mutual interests of its members, financially, scientifically and to build up a better ethical relationship between the two professions. Bi-monthly meetings will be held and the following officers have been elected: President, M. B. Loeb; vice-president, G. Azoff; secretary, Dr. Harry S. Snyderman; treasurer, Dr. Harry A. Stembler.——At a banquet February 6, the Northwestern Medical Society changed its name to "The Philadelphia Clinical Association," and elected the following officers: president, Dr. G. Morton Illman; vice-president, Dr. J. Edward Wallis; secretary, Dr. Harry Hudson; treasurer, Dr. William McKeage; executive committee, Drs. Harry A. Duncan, Daniel Longaker and Moses Behrend; board of censors, Drs. Samuel M. Wilson, Lewis S. Somers and Winslow Drummond.——The new officers for 1911 for the section on otology and laryngology of the College of Physicians are Dr. Arthur W. Watson, chairman, and Dr. Ralph Butler, clerk.——At the recent meeting of the Physicians' Motor Club, the following officers were elected for 1911: president, Dr. S. Leon Gans; vice-presidents, Dr. L. Webster Fox, Dr. J. J. Rebrecht, Dr. Richard C. Norris; secretary, Dr. J. Gurney Taylor; treasurer, Dr. Lewis H. Adler, Jr.; solicitor, B. Douglas Bartlett; directors for 3 years: Drs. Sylvester J. Deehan and H. Augustus Wilson; for 2 years: Drs. Ernest W. Kelsey and Francis J. Kelly; for 1 year: Drs. T. J. Ellinger and E. S. Saylor; for four years: Drs. Charles R. Haig, Jr., and Ellwood R. Kirby.——The section on ophthalmology of the College of Physicians elected Dr. William M. Sweet chairman and Dr. Thomas B. Holloway, clerk.

TEXAS

Medical Association Organized.—The Lavacca County Medical Association has been organized at Halletsville with Dr. Paul Renger, president, and Dr. W. W. Shropshire, secretary.

State Board Election.—At the first meeting of the State Board of Medical Examiners, held in Austin, February 7, organization was perfected and the following officers were elected: president, Dr. William B. Collins, Lovelady; vice-president, Dr. Marquis E. Daniel, Honey Grove, and secretary, Dr. John D. Mitchell, Fort Worth.

State Board Appointments.—Dr. Ralph Steiner, Austin, has been appointed state health officer, and Drs. Benjamin M. Worsham, El Paso; William L. Crosthwaite, Holland; William B. Collins, Lovelady; George L. Baber, Winnsboro; John H. Evans, Palestine, and James D. Osborn, Cleburne, members of the State Board of Health, and John E. Rosser, Austin, registrar of vital statistics.

Personal.—In a fire at Rusk, recently, Drs. Andrew H. McCord and John F. Johnson lost their office furniture, books and instruments.——Dr. Robert M. Wickline has succeeded Dr. Louis H. Kirk, resigned, as health officer of Austin.——Drs. Hugo V. Heblin, Fort Worth, and I. Newton Suttle, Corsicana, have been appointed first lieutenants and assistant surgeons in the Medical Corps, Texas National Guard.

New Sanitariums.—Dr. Frank L. Barnes, Trinity, is about to erect a sanitarium at Trinity to cost $15,000.——Dr. Francis G. Floeckinger is building a sanitarium in Taylor, to cost $15,000.——Dr. James A. Caldwell, McKinney, has let the contract for his new sanitarium which is to be completed in May.——The control of the Baptist Sanitarium, Houston, has formally passed to the new company, to which a charter has been issued under the name Baptist Sanitarium and Hospital.

GENERAL

New President of Sanitary Commission.—Dr. Meverell K. Allen, Louisville, has been elected president of the Ohio River Sanitary Commission, vice Dr. Robert E. Vickers, Huntington, W. Va., resigned.

Physicians to Meet.—The twenty-third semi-annual meeting of the Missouri Valley Medical Society will be held in St. Joseph, Mo., March 16-18, under the presidency of Dr. Donald Macrae, Council Bluffs, Ia. Drs. Charles H. Mayo, Rochester, Minn., and Heinrich Stern, New York City, will deliver the addresses on surgery and medicine, respectively.——It is announced that the next annual meeting of the Association of State and Territorial Health Officers will be held in San Francisco, June 24-26, and that a joint meeting of the health officers of the United States and Canada will follow.——The fourteenth annual meeting of the American Gastro-Enterological Association will be held in Philadelphia, April 19 and 20. Among the more important papers on the preliminary program are those on "Stretching of the Pylorus in Benign Stenosis," by Dr. Max Einhorn, New York City; "Operative Treatment of Impermeable Cardiospasm," by Dr. Willy Meyer, New York City; "The Relation of Symptoms to Pathologic Findings in Cancer and Ulcer of the Stomach," by Dr. Joseph C. Bloodgood, Baltimore, and papers on "Duodenal Ulcer," by Drs. John A. Lichty, Pittsburg; James T. Pilcher, Brooklyn, N. Y., and Lewis Brinton, Philadelphia.

Manufacture and Distribution of Meningitis Serum.—The Rockefeller Institute for Medical Research now gives notice that it has discontinued the general distribution of antimeningitis serum which it has undertaken without charge ever since the discovery of this remedy, and will now devote to other lines of investigation the funds hitherto needed for gratuitous distribution of the serum, handing over to the public health authorities of municipalities and states, and to commercial establishments the routine preparation of the serum for general use. The Board of Health of the City of New York has undertaken the regular production of the serum and will provide for free distribution to all hospitals and to all physicians who apply for it. Statistics show that the death rate from cerebrospinal meningitis has been reduced to less than one-third of its former amount by the early use of antimeningitis serum. The serum is administered by being injected into the spinal canal by means of lumbar puncture, an operation which is also required to secure the fluid for bacteriologic diagnosis, and several separate injections are required in treating a patient. The effective employment of the serum is likely therefore to be restricted on account of the experience and skill required in the administration, and the high cost of the commercial product, unless the preparation, distribution, and, when necessary, administration are undertaken by state and municipal authorities.

Memorial to the Late Dr. Howard T. Ricketts.—The Mexican government has had Dr. Ricketts' works on Mexican typhus collected and published in Spanish in a handsome volume of over 135 pages entitled, "Howard Taylor Ricketts y sus Trabajos sobre el Tabardillo," with portrait and tribute to the memory of "the heroic research worker who died in consequence of tabardillo contracted in the course of his study of that disease." The volume contains the official documents relating to his death, his special articles written in collaboration with Dr. Russell M. Wilder on the etiology of the disease, and which were published in THE JOURNAL, and, thirdly, the addresses delivered at the unveiling of the memorial tablet in the laboratory at Mexico where Dr. Ricketts had carried on part of his research work. Copies of the memorial volume are to be presented by the Mexican government to the "principal universities, scientific societies, libraries and medical publications of the nations friendly to Mexico, and also to all the national Mexican scientific institutions." The volume opens with the official communication from the secretary of the department to Mrs. Ricketts informing her that the laboratory in which Dr. Ricketts had worked was to be renamed after him, that the scientific institutes in the City of Mexico were to be draped in mourning for three days, that a representative body of members of the faculties was to attend the funeral and cablegrams of condolence sent to the presidents of the universities of Chicago and Pennsylvania; the replies received are also given.

FOREIGN NEWS

Centennial of the Stockholm Medical School.—The Karolinska Medico-Kirurgiska Institutet at Stockholm recently celebrated its hundredth anniversary, concluding the festivities with the bestowing of honorary degrees on a number of foreign scientists. Five members of the faculty are on the board which awards the Nobel prizes.

The Nobel Prizes.—As our readers know, the Nobel prize fund awards five prizes each year averaging from $38,000 to $40,000 each. Since 1900 nearly two millions have been thus distributed to leaders in physics, literature, promotion of peace, medicine and chemistry. The list of the scientific recipients forms an international Hall of Fame, the chemists thus honored being van't Hoff, E. Fischer, Arrhenius, Ramsay, Baeyer, Moissan, E. Buchner, E. Rutherford, W. Ostwald, and the 1910 recipient, O. Wallach, professor of chemistry at the university of Göttingen. The recipients of the medicine prize have been von Behring, D. Ross, Finsen, Pawlow, Koch, Cajal and Golgi, Laveran, Ehrlich and Metchnikoff, Kocher and the latest recipient, A. Kossel, professor of physiology at the university of Heidelberg. The last physics prize was awarded to van der Waals, professor of physics at the university of Amsterdam, the last literature prize to P. J. L. Heyse of Germany, and the peace prize to the International Peace Bureau at Berne. The balance between the various countries has been maintained with remarkable impartiality but the majority of the prizes have gone to Germany. Only two have crossed the Atlantic, the peace prize given to President Roosevelt and the physics prize in 1907 to Professor Michelsen of the University of Chicago. It is a question whether the design of the founder of the prize fund has been realized to date; the awards have gone to men who were already resting on their laurels and the prizes have not served to foster new research to any extent. The committee in charge of the awards pays no attention to personal applications for prizes; the applications to be considered must come from scientific societies, institutions or other organized authority. It is possible that the greater preponderance of prize-winners in certain nationalities is because their institutions and societies have taken greater pains to present the claims of candidates in their respective nations.

CANADA

Brown Memorial Fund.—More than $10,000 has been subscribed to the memorial fund of the late Dr. Arthur A. Brown, Montreal, and it has been decided to endow a scholarship at McGill University.

Investigation of Typhoid Fever in Lumber Camps.—Senator De Veber, M.D., has secured an appropriation of $500 from the Dominion government for his committee to investigate typhoid fever in lumber and railway construction camps.

New Provincial Board of Health.—The following comprises the new Board of Health of the Province of Ontario: Chairman, Dr. Adam H. Wright, Toronto; chief health officer of the province and secretary of the board, Dr. J. W. S. McCullough, Toronto; and Drs. David B. Bentley, Sarnia; George Clinton, Belleville; William H. Howey, Sudbury, and James Roberts, Hamilton.

Hospital Notes.—Arrangements have been made whereby the Protestant Hospital for the Insane, Quebec, will receive $142 per patient each year from the government for a period of fifteen years.——In a suit brought for damages by a patient of Notre Dame Hospital, the hospital has won the victory.——The Charlotte Eleanor Englehart Hospital, Petrolia, has recently been opened.

Plans of Toronto Health Officer.—Dr. Charles J. C. O. Hasting, medical health officer of Toronto, estimates the expenses of his department at $159,000 for the current year. He contemplates the reorganization of the Toronto Health Department, the establishment, in addition to the chief of laboratories, of a secretary of health, bureaus of vital statistics, contagious disease and food inspection, hospital and ambulance service, and sanitation and a school for sanitary instruction.

Personal.—Sir Wilfred Thomaston Grenfell, the medical missionary of the Labrador coast, has been selected as the William Belden Noble lecturer at Harvard University for 1911 and 1912.——Dr. George R. McDonagh, Toronto, is taking a trip to Barbados.——Dr. William E. Struthers, Toronto, has been appointed chief medical inspector of schools.——Dr. John N. E. Brown, superintendent of Toronto General Hospital, has resigned and will study hospital administration abroad.——Dr. Fred J. Tees has resigned as superintendent of the Montreal General Hospital, and has been succeeded by Dr. George Shanks.——Dr. Louis Laberge has been retained as health officer of Montreal.

Toronto Demands License Power.—The dean of the Medical Department of Toronto University, in his annual report, advocates that the power of the Ontario Medical Council be curtailed as regards the standard of medical education and examination. He claims that the work of the medical department is hampered, owing to the fact that the council does not set a high standard for qualification and examination. An effort is being made by the university authorities to have the legislature pass an act whereby a graduate in medicine from Toronto University may enter at once into the practice of medicine without any further examination by the council.——A delegation from Queen's University, Kingston, has gone to Toronto to oppose the application of Toronto University that it be allowed to grant licenses to its graduates to practice medicine without passing the examination of the Ontario Medical Council.

PARIS LETTER

(From Our Regular Correspondent)

PARIS, Jan. 27, 1911.

The Candidacy of Mme. Curie and the Election of Dr. Branly to the Academy of Sciences

The candidacy of Mme. Curie (THE JOURNAL, Jan. 7, 1911, p. 53) brought up the question of the eligibility of women to the Institut de France, which was warmly discussed at the quarterly session of the five academies. A resolution was finally passed to the effect that it appeared altogether wise to respect immutable tradition on this point, but that the assembly did not assume to prescribe this course to the various individual academies. The Académie des sciences therefore presented Mme. Curie in the first rank of the list of candidates in the section of physics; in the second rank were presented Dr. Branly and four other candidates, among them Dr. Broca, *agrégé* professor at the Faculté de médecine, On January 23, the academy held the election. The contest narrowed down to Mme. Curie and Dr. Branly. There were fifty-eight voters. On the first ballot, Mme. Curie received twenty-eight votes and Dr. Branly twenty-nine. Dr. Branly, having received thirty votes or a majority on the second ballot, was elected.

Edouard Branly was born in Amiens in 1846. He received the degree of doctor of science in 1873, and was soon appointed professor of physics at the Institut catholique. In 1882, he received the degree of doctor of medicine. The researches which have brought him his greatest renown pertain to radioconductivity and thereby to wireless telegraphy. It may be said that the latter was rendered possible by the work of Branly, and the fact has been recognized by Marconi himself. If, as d'Arsonval says, every academy, whatever the number of its sections, really comprises only two classes of members, those who honor it, and those who are honored by it, it must be acknowledged that Branly belongs incontestably to the first category.

Salvarsan (606) and Syphilitic Nephritis

In the session of the Société médicale des hôpitaux, on January 20, Professor Widal and M. Javal made a report on the treatment by salvarsan of a patient with syphilitic nephritis, who for fourteen months had had an abundant albuminuria of from 10 to 14 gm. per liter. In the seven days following the administration of the drug (0.6 gm. by intravenous injection) the albuminuria presented no appreciable change; from the eighth to the seventeenth day it diminished from 10 gm. to 2.5 gm. per liter and in the following month, with slight oscillations, it continued to decrease from 2.5 gm. to 1 gm. It should be said that the patient had been treated, at the beginning of the nephritis, by several injections of biniodid of mercury, which had no action on the kidney. Salvarsan appeared on the contrary, to effect a decrease of the albuminuria, but it should not be forgotten that the two treatments were applied at very different periods of the affection; the mercury, at the moment of the edema and the greatest retention of chlorids; the salvarsan, when the renal permeability to chlorids had been much improved. It is probable that salvarsan does not produce the same effects at all periods of syphilitic nephritis. In any case, although the state of the kidney should be taken into account in treatment by salvarsan, incipient syphilitic nephritis being regarded as a contra-indication, this does not apply indiscriminately to all forms of renal syphilis or to all the periods of the disease.

Dr. Siredey has observed a patient affected with albuminuria, edema of the legs and purpura, in whom, six months after an indurated chancre, a sclerogummatous glossitis appeared. Mercury treatment was inefficacious and appeared to increase the albuminuria; an injection of salvarsan was employed. Seven days afterward a very marked improvement of the glossitis and a diminution of the albuminuria was observed.

Portraits at the Pasteur Institute

A portrait of Dr. Roux in his laboratory is about to be placed in the library of the Institut Pasteur, by the side of the bust of Pasteur, by Paul Dubois, and the portraits of Duclaux and Metchnikoff. Around these portraits are to be the busts of the benefactors of the institute, among whom are Alexander III, who was one of the first subscribers, Dom Pedro, second emperor of Brazil, Baron Alphonse de Rothschild, Osiris and others; then those of the former collaborators of Pasteur, Grancher, Nocard and Chamberland. The portraits of the last-named are by Dr. Paul Richer, member of the Académie de médecine and the Académie des beaux-arts.

Election of Dr. Sébileau to the Academy of Medicine

On January 24, the Académie de médecine elected a member in the section of anatomy and physiology to replace Professor Gréhant, who died last March. On the first ballot, Dr. Sébileau, *agrégé* professor of the Faculté de médecine de Paris and surgeon of the hospitals, was elected by forty-five votes against thirty-seven for Dr. Prenant, professor of histology at the Faculté de médecine de Paris.

Prizes Offered by the Belgian Academy of Medicine

The Académie royale de médecine de Belgique has offered a prize of 800 francs ($160) each, for studies on the following questions: (1) experimental research on the modifications produced in the peripheral and central parts by injections of alcohol into the nerve trunks; (2) a study of the lesions produced by hydrogen phosphid poisoning. The close of the competition is fixed for Feb. 15, 1912.

BERLIN LETTER

(From Our Regular Correspondent)

BERLIN, Jan 19, 1911.

Personal

Professor Nagel, director of the physiologic institute at Rostock, has just died at the age of 40. He joined the faculty of Tübingen in 1895 and after a short stay at Freiburg he was made head of a department in the physiologic institute in Berlin in 1902 whence he was called to Rostock as regular professor in 1908. The chief field of this gifted investigator was comparative physiology and the physiology of the senses. ——Professor Matthes, director of the clinic for internal medicine at the Cologne academy for practical medicine, has accepted the call to succeed Professor Brauer at Marburg.——Professor Uhlenhuth, of the imperial health office, has received a call to Strasburg as successor to Professor Forster.——Dr. Moro, privat-docent at Munich, has assumed the supervision of the Heidelberg pediatric clinic in place of Professor Feer who has gone to Zurich.

Transfer of the Prussian Medical Bureau From the Department of Education to the Department of the Interior

Medical affairs in Prussia have not, as in some other states, a special department and an independent position, but for many years have been attached to the so-called Kultusministerium, which has charge of ecclesiastical and educational matters. In consequence of the overloading of this department, the effort has repeatedly been made to separate the medical department from the Kultusministerium and transfer it to the department of the interior. In fact, the medical bureau originally belonged to the department of the interior, having been transferred to the department of education in 1849. Various reasons for and against the change have been urged, but the prevailing motive aside from the overloading of the Kultusministerium was the fact that the medical police was already a part of the department of the interior, and it was felt best that all medical affairs should be under one management. To the medical bureaus are subordinated in the first place the highest Prussian expert authority on medicine, namely the scientific deputation for medical affairs, and also the institute for infectious diseases in Berlin and a number of hygienic institutes in provincial cities, the medical investigation offices in the provinces, etc. This change cannot be considered of great importance. It will depend on the personality of the medical department and also on the head of the department of the interior whether matters of health and those affecting the medical profession will be conducted in the same way as before or not. No restriction in the requirements of the health office is to be feared, for any state which does not keep at the front in these matters would in a certain sense saw off the branch on which it is sitting.

A Salaried Municipal Medical Councilor in Berlin

The municipal health affairs of Berlin have heretofore not been conducted by a salaried member of the city government but by a physician who had merely the honorary position of a municipal councilor. The colleague in question has undeniably shown a good capacity for organization, but in consequence of an insufficient preparation has for a long time been unequal to the task of managing so great a community as our metropolis is bound to present. For many years the Berlin medical profession and the medical press, especially the *Deutsche medizinische Wochenschrift*, have demanded that the medical affairs in this city shall receive the same representation that is received by the building interests, the schools, etc., which means that they shall be cared for by a salaried officer specially trained' for this important position, who shall give his attention exclusively to the care of the public health. This demand has heretofore been refused by the city government which has been under the direction of a mayor who showed little comprehension of medical needs. Some recent occurrences which indicated the insufficiency of the organization, but especially the example of our neighboring city, Charlottenburg, which has established a municipal health officer, appears to have secured the fulfilment of the wishes of the Berlin medical profession. The commission on municipal hospitals, a few days ago, made the proposal to appoint a salaried municipal health officer with the salary of a technical member of the city government, inasmuch as the duties imposed on the city in the field of public health and the tasks voluntarily assumed in this relation have lately reached such extent and importance that it seems necessary, in addition to the member who is filling the honorary office, to secure another of distinguished ability in all such questions.

Antivaccination Movement

Ever since the introduction of compulsory vaccination its opponents have each year endeavored to have the law repealed, and they seek to gain the favor of the government, the parliament and the public for their efforts by collecting and displaying the actually observed injuries due to vaccination and also by appeals to the imaginary horrors of vaccination. Repeatedly the government has seen fit to appoint commissions before which the antivaccinationists, to whom also some physicians belong—were given opportunity to make their complaints, and regularly the result of these conferences has been that the provisions for vaccination have been improved but the provisions of the vaccination law itself have been maintained. Lately the antivaccinationists have made a new attack and have induced two delegates of the center to make a motion that another commission be appointed to discuss a modification of the vaccination law. It is further demanded that a bill should be prepared in which it shall be provided that the present physical compulsion for carrying out vaccination be removed and that further a so-called conscience clause be introduced according to which any person shall be exempt from vaccination, if he declares before the appropriate official that he cannot reconcile the vaccination of the child with his conscience. It is clear that with the adoption of such a conscience clause, compulsory vaccination would be completely abrogated and that hundreds of thousands who are opposed to vaccination, from ignorance and superstition, would exempt their children from it. The experience gained with such a conscience clause in England, where it has existed since 1907, will, it is to be hoped, induce the Reichstag to refuse the proposal of the antivaccinationists. In England marked small-pox epidemics still occasionally develop which cause numbers of deaths. The high small-pox morbidity and mortality which occur in countries in which compulsory vaccination is not required, should easily induce the government to withhold its consent to such a proposal even if it should be adopted by the Reichstag.

Imports and Exports of Drugs and Medicinal Chemicals

In 1909 the importation of manufactured remedies and other pharmaceutical products was 285 tons, valued at $290,000 (1,140,000 marks); in 1908, 326 tons at a value of $413,000 (1,653,000 marks). The exports, in 1909, were: 1,109 tons at a value of $1,994,000 (7,979,000 marks); in 1908: 936 tons at a value of $1,742,000 (6,968,000 marks). The best customers are Austria, Russia and the United States.

Chemical products for use in medicine were imported as follows: 1909: 60 tons valued at $178,000 (714,000 marks); 1908: 44 tons valued at $133,000 (532,000 marks). The exportations were: 1909: 915 tons valued at $3,223,000 (12,844,000 marks); 1908: 837 tons valued at $2,803,000 (11,212,000 marks).

Marriages

Oscar D. Whalin, M.D., to Mrs. Emma Maxwell, both of Chicago, recently.

Clayton McPeek, M.D., to Miss Mary Alice Biddle, both of Columbus, O., January 30.

Walter Benjamin Harvey, M.D., Pittsburg, to Miss Aurelia F. Bartlett of Lewisville, Ind., February 1.

David Henry Worthington, M.D., Aurora, Ill., to Miss Huldah Henrietta Bettcher, at Iowa City, Ia., January 17.

Deaths

Edward Gamaliel Janeway, of New York City, eminent internist and specialist on diseases of the mind, died at his summer home in Summit, N. J., February 10, aged 69. He was born near New Brunswick, N. J., and received his preliminary education at Rutgers College, from which he received the degree of B. A. in 1860, and M. A. in 1863. While still a student in the College of Physicians and Surgeons, he entered the United States Army as a medical cadet, serving in a hospital in Newark, N. J., in 1862 and 1863. In 1864 he was graduated from the College of Physicians and Surgeons. He was curator of the institution from 1868 to 1872, professor of pathology and practical anatomy from 1872 to 1879, and professor of diseases of the mind and nervous system from 1881 to 1886; professor of medicine in Bellevue Hospital Medical College from 1886 to 1892, and dean of the University and Bellevue Hospital Medical College since 1908.

He was a member of the American Medical Association, National Association for the Study and Prevention of Tuberculosis, Association of American Physicians, New York Academy of Medicine, and many other learned societies. From 1875 to 1882, he acted as commissioner of the Health Department of New York City. He was on the staff of Bellevue, Mount Sinai, Presbyterian, St. Vincent, J. Hood Wright, Woman's and French hospitals, and on the staff of the Hospital for the Ruptured and Crippled as consulting physician. He was given the degree of LL.D. by Rutgers College in 1898, by Columbia University in 1904, and by Princeton University in 1907. In 1876 Dr. Janeway served as president of the *New York Medical Journal* Association. By the death of Dr. Janeway, the medical profession loses one of its best internists and a pioneer in the practical crusade against tuberculosis.

Stanley Douglas Curran, M.D. Bellevue Hospital Medical College, 1896; instructor in physical diagnosis in the University and Bellevue Hospital Medical College; attending physician to the clinic of that institution and to the Harlem Dispensary; adjunct physician to Washington Heights Hospital; died at his home in New York City, February 4, from a gunshot wound of the head, self-inflicted, it is believed with suicidal intent, while despondent on account of ill health, aged 40.

John Calvin McClung, M.D. Western Reserve University, Cleveland, 1873; a member of the American Medical Association; formerly a member and president of the board of education, mayor, member of the council, and health officer of Leipsic, O.; local surgeon for the Cincinnati, Hamilton and Dayton; New York, Chicago, and St. Louis, and D. T. and I. railways; died at his home, February 3, from cerebral hemorrhage, following an attack of influenza, aged 68.

Aristides Monteiro, M.D. Medical College of Virginia, Richmond, 1850; Jefferson Medical College, 1854; formerly physician in charge of the male department of the Eastern State Hospital, Williamsburg, Va.; surgeon of the Tenth Virginia Cavalry and later surgeon to Col. Mosby's command in the Confederate service during the Civil War; afterward editor of a weekly newspaper in Manchester; died at his home in Richmond, January 27, aged 82.

Charles Chesterfield Nicola, M.D. University of Michigan, Ann Arbor, 1897; a member of the American Medical Association; for several years a staff physician of the Battle Creek Sanitarium; superintendent of the New England Sanitarium, Attleboro, Mass.; while en route to New York from Bermuda where he had gone on account of his health, disappeared from the steamer *Oceana*, February 7, and is supposed to have been drowned, aged 44.

Charles Edwin Wood, M.D. University of Michigan, Ann Arbor, 1907; who entered the U. S. Public Health and Marine-Hospital Service as assistant surgeon in 1908, and was assigned to duty on the U. S. R. C. *Seneca* but resigned from the service in 1910; a member of the American Medical Association; physician to the Brooklyn Rapid Transit Employees' Benefit Association; died in the Brooklyn Hospital, February 1, from Ludwig's angina, aged 29.

Giles Bertram Allen, M.D. University of Michigan, Ann Arbor, 1867; a member of the Michigan State Medical Society; a veteran of the Civil War; formerly a member of the legislature; probate judge of Eaton County for six years, and a member of the school board of Charlotte for fifteen years, and for several years a member of the local pension board; died at his home, February 5, from heart disease, aged 67.

Jacob Coble, M.D. Medical College of Indiana, Indianapolis, 1885; a member of the Indiana State Medical Association; a veteran of the Civil War; for more that forty years a practitioner of Spencer, Ind.; local surgeon for the Pennsylvania System; a member of the district board of pension examiners; died at his home, February 4, from heart disease, aged 66.

Joseph Frederick Sommerhoff, M.D. Bellevue Hospital Medical College, 1894; for ten years chairman of the examining board of the New Jersey College of Pharmacy; and at one time professor of hygiene in that institution; for many years a practitioner of Newark; died at the home of his sister in Bloomfield, N. J., January 25, from locomotor ataxia, aged 45.

J. Elmer Bailey, M.D. *Kentucky University, Louisville, 1904;* formerly local surgeon at Huttig, Ark., for the Eldorado and Bostrop, Farmerville and Southern, and Little Rock and Monroe railroads; a member of the Union County Board of Health; died at his home in Strong, Ark., January 12, from typhoid fever, aged 39.

Reynaldo Dorsey Mackin, M.D. Medical College of Ohio, Cincinnati, 1887; a member of the American Medical Association; a member of the legislature of West Virginia in 1907 and 1908; local surgeon at Grafton for the Baltimore and Ohio Railroad; died at his home, January 31, from nephritis, aged 46.

John Wesley Bickford, M.D. University of Buffalo, N. Y., 1881; a member of the American Medical Association; formerly coroner of Niagara County and city physician of Lockport, N. Y.; jail physician since 1908; died at his home in Lockport, January 31, from cerebral hemorrhage, aged 62.

John Grimes Keller, M.D. Medical College of Georgia, Augusta, 1884; for two years quarantine officer of Savannah; later port surgeon and county physician; in 1902 and 1904 and 1910 coroner of Chatham County; died at his home in Savannah, January 26, from cerebral hemorrhage, aged 48.

Adolph Rosenthal, M.D. University of Vienna, Austria, 1869; for eight years a surgeon in the Austrian service; of Uniontown, Pa.; from 1882 to 1902, a practitioner of Chicago; died in Mount Sinai Hospital, New York City, January 12, two weeks after an operation for pyonephrosis, aged 65.

William Litchworth Birney, M.D. Missouri Medical College, St. Louis, 1879; a member of the Missouri State Medical Association; for half a century a practitioner of medicine, and for forty years a resident of Hydesburg, near Hannibal; died at his home, January 29, from pneumonia, aged 79.

James T. Estill, M.D. Missouri Medical College, St. Louis, 1879; surgeon for the Denver and Rio Grande Railroad at Colorado Springs, Colo.; died at his home in that city, while endeavoring to light a gas range, February 2, from the accidental inhalation of gas flames, aged 61.

Selden M. Payne, M.D. Eclectic Medical Institute, Cincinnati, 1846; assistant surgeon of the Ninety-Fourth Illinois Volunteer Infantry during the Civil War; died at his home in Lexington, Ill., January 18, from injuries received by a fall down stairs two weeks before, aged 91.

Alfred Elisha Hubbard, M.D. College of Physicians and Surgeons, New York City, 1892; of Brooklyn, N. Y.; for a year surgeon on steamers plying between Hamburg and New York; died in the Norwegian Hospital, Brooklyn, Dec. 26, 1910, from meningitis, aged 41.

Charles Albert Gaudet, M.D. Tulane University, New Orleans, 1869; a member of the American Medical Association; a Confederate veteran; at one time a member of the board of health of New Orleans; died at his home, February 1, from pneumonia, aged 63.

William L. Bowman (license, Nebraska, 1891); a pioneer practitioner and clergyman of northeastern Nebraska, where he had practiced for more than forty years; for one term judge of Stanton County; died at his home in Stanton, February 6, aged 86.

Stephen S. Stout (license, years of practice, Michigan, 1900); surgeon of volunteers during the Civil War; for more than forty years a practitioner of Cheshire; a member of the state legislature in 1899; died at his home, January 31, aged 81.

Platt Ellsworth Beach, M.D. Long Island College Hospital, Brooklyn, 1877; a member of the American Medical Association; died at his home in Seville, O., January 15, from septicemia, due to a splinter wound of the left thumb, aged 55.

John N. W. Crawford, M.D. Medical College of Ohio, Cincinnati, 1880; formerly of Portsmouth, O., but for the last ten years a resident of Geneva, Switzerland; died in Cairo, Egypt, Dec. 30, 1910, from pernicious anemia, aged 53.

Joseph Milligan Wallace, M.D. Columbus (O.) Medical College, 1879; a member of the Illinois State Medical Society, and one of the oldest practitioners of Mercer County; died at his home in Aledo, February 1, from pneumonia, aged 56.

Alfred Charles Denham, M.D. Miami Medical College, Cincinnati, 1867; for many years a practitioner of Somerset, Ky., and Cincinnati; died at the home of his daughter in the latter city, January 11, from cerebral hemorrhage, aged 81.

John M. Bradford, M.D. University of Pennsylvania, Philadelphia, 1884; at one time a member of the staff of the Episcopal Hospital, Philadelphia; died in his office in Kensington, Philadelphia, February 2, from nephritis, aged 52.

William R. Nugent, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1863; formerly chief surgeon of the Iowa Central Railroad at Oskaloosa, Ia.; died at his home in Chicago, February 3, from chronic nephritis, aged 78.

Carl William Rummel, M.D. Rush Medical College, 1899; a member of the Iowa State Medical Society; health officer and city physician of Webster City, Ia.; died at his home, January 31, from pneumonia, aged 37.

Charles W. Vroom, M.D. State University of Iowa College of Homeopathic Medicine, Iowa City, 1887; a member of the Iowa State Medical Society; died at his home in Whitten, Ia., January 9, from myocarditis, aged 61.

Fenwick Robertson, M.D. University of Maryland, 1854; assistant surgeon in the Confederate service during the Civil War; died at the Maryland Line Confederate Soldier's Home, Pikesville, Md., January 31, aged 81.

William Ely, M.D. Western Reserve University, Cleveland, 1881; a member of the Medical Society of the State of Pennsylvania; died at his home in Beaver Center, January 12, from cerebral hemorrhage, aged 62.

Thomas Zadoc Offutt, M.D. University of Pennsylvania, Philadelphia, 1856; surgeon in the Confederate service during the Civil War; died at his home in Granite, Md., January 30, from senile debility, aged 81.

Joseph L. Cook, M.D. Jefferson Medical College, 1858; formerly president of the Westmoreland County (Pa.) Medical Society, and coroner; died at his home in New Alexandria, January 19, aged 79.

Charles L. Morehouse, M.D. Eclectic Medical College of the City of New York, 1881; for sixty-four years a practitioner; died at his home in New York City, January 23, from pneumonia, aged 88.

Samuel Micajah Johnson, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1873; a veteran of the Civil War; died at his home in Carson, Ia., January 24, from cirrhosis of the liver, aged 70.

Joseph Gardner Moore, M.D. Baltimore Medical College, 1906; a member of the American Medical Association; died at his home in Philadelphia, Dec. 16, 1910, from typhoid fever, aged 33.

Clement Ritter, M.D. Jefferson Medical College, 1890; of Selma; a member of the Medical Association of the State of Alabama; died at an infirmary in Birmingham, January 11, aged 47.

George L. Hughes, M.D. Hahnemann Medical College, Chicago, 1891; died at his home in Chicago, February 9, after an operation for bladder disease, from heart disease, aged 72.

John P. Cook (license, years of practice, Texas, 1907); a Confederate veteran; for thirty-five years a practitioner; died at his home in Mexia, Tex., Oct. 1, 1910, from cholelithiasis, aged 66.

Edward Paulding, M.D. Bellevue Hospital Medical College, 1890; a physician of New York City; died at his home in Flushing, L. I., January 10, from cerebral hemorrhage, aged 48.

Henry J. Denham (license, Rhode Island, 1895); for more than a quarter of a century a practitioner of Providence; died at his office in that city, January 20, from heart disease.

John B. Baskerville, M.D. University of Pennsylvania, Philadelphia, 1869; of Dublin, Va.; a Confederate veteran; died at the home of his daughter in Dublin, January 17, aged 64.

Robert Swayne Prentiss, M.D. College of Physicians and Surgeons, New York City, 1870; died at his home in Long Island City, N. Y., January 28, from angina pectoris, aged 71.

Lemuel Leake Silverthorn (license, years of practice, Illinois, 1877); for fifty-four years a practitioner of Illinois; died at his home in Charleston, January 21, aged 79.

Samuel T. F. Kirkpatrick, M.D. Reform Medical College of Georgia, Macon, 1861; formerly of Franklin, Tenn.; died at his home in Nashville, January 26, aged 72.

Thomas Benjamin Haynes, M.D. Kentucky School of Medicine, Louisville, 1890; died at his home in Beaumont, Tex., January 27, from dysentery, aged 44.

Thomas Floyd Norvell (license, Illinois, 1878); for thirty-five years a practitioner of Illinois; died at his home in Peoria, January 24, from nephritis, aged 58.

William M. Rich (license, Kansas, 1901); for twenty-six years an eclectic practitioner of Clements; died at his home, January 27, from influenza, aged 81.

Alfred Stevens, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1874; died at his home in Iowa City, January 27, from cerebral hemorrhage, aged 71.

Isaac D. Johnson, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1852; died at his home in Kennett Square, Pa., January 30, aged 83.

James Polk Marshall (license, Arkansas, 1903); an eclectic practitioner of Caulksville, Ark.; died at his home, January 29, from heart disease, aged 65.

John A. Fitz-Gerald (license, Illinois, 1897); was found dead in his office in Chicago Heights, January 23, from valvular heart disease, aged 45.

Otto Albert Pfefferkorn, M.D. Boston University, 1910; died at his home in East Weymouth, Mass., January 28, from pneumonia, aged 24.

James R. Rowland, M.D. Texas Medical College, Galveston, 1875; died at his home in Mineola, Tex., Oct. 4, 1910, from cancer, aged 71.

"The Propaganda for Reform"

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION.

THE GLUTEN AND CARBOHYDRATE CONTENTS OF GLUTEN BREAD

At the Second International Congress for the Repression of Frauds, held in Paris, the proceedings of which are published by the Geneva White Cross Society, the question of the gluten and carbohydrate content of gluten bread was discussed. An abstract of this part of the society's proceedings, is given below, and the matter is further referred to editorially in this issue:

BREAD AND BAKERS' PRODUCTS

The following definition was proposed: "Gluten bread is bread made from a flour containing at least 60 per cent. gluten, this flour being obtained either by eliminating a part of the starch of the flour or by mixing a gluten flour with it."

Dr. Chevalier: The name gluten bread ought to be applied only to bread containing a maximum of 25 per cent. carbohydrates, starch, sugar or derivatives and 75 per cent. nitrogenous substances. According to Hewald, in fact, gluten bread ought to contain about 76 per cent of nitrogenous substances and 10 to 30 per cent. of carbohydrates. This means that in place of fixing a minimum of gluten or nitrogenous substances, one fixes a maximum of carbohydrates which is really more logical, for what the diabetic seeks is a food which is not a carbohydrate.

Pharmacien Principal Pairault: No doubt, but the question is very complicated.

The President: The definition of 60 per cent. of gluten is really the definition of the inventor of gluten bread, Bouchardt, who remarks that in his time a gluten bread was manufactured to which "legumine" was added, and which was sold under the name of "gluten and legumine bread."

M. Arpin: The definition is completed as follows: "In the above-mentioned breads the nitrogenous substances may be furnished by gluten, aleurone, casein, legumine, almonds, soya flour with oils removed, etc., but the presence or the association of these various substances ought to be specified." Consequently this would be an optional operation. That is another question which will come afterward. It is necessary first to complete the definition.

Dr. Chevalier: This quantity of gluten is not sufficient to justify the name of "gluten bread." Here are analyses published by M. Balland. He analyzed three gluten breads; they have the following compositions: The first two are very similar. They contain 36 per cent. nitrogenous substances; 1.25 and 1.76 per cent. of fat and 51.87 per cent. of starch for the first, and 52.92 per cent for the second. These are the commercial breads which exist at present. The third has the following composition:

Moisture	10.00 per cent.
Albuminoid nitrogenous substances	73.02 per cent.
Fat	3.45 per cent.
Starch	12.50 per cent.

It is evident that the first two breads cannot be considered gluten bread. There is nothing gained over a definition which is altogether therapeutic, and this is the point of view which I take. To give a patient gluten bread without any addition is not possible, but if you make bread with gluten and wheat flour you obtain too large a proportion of carbohydrates and therefore a bad bread. It is necessary to add either legumine or other nitrogenous substances containing a sufficiently large proportion of nitrogen to permit of the making of bread. From the therapeutic point of view, you ought to base the definition on the quantity of carbohydrates and not on the quantity of gluten.

Pharmacien Principal Pairault: Is it possible to manufacture bread with pure gluten? No! Then it must be admitted that there is a certain proportion of starch. What minimum proportion do you think possible from the practical point of view, from the bakers' point of view?

M. Arpin: Bread is made with pure gluten; I have seen it. But one needs to know if this bread can be easily masticated and digested by the diabetic.

Dr. Chevalier: [illegible] the practical point of view, I demand a maximum of 2[illegible] of carbohydrates in gluten bread.

The President: This is what Bouchardt says in his book: "In the manufacture of gluten bread, the most conscientious manufacturers put in 25 per cent. of wheat flour and 75 per cent. of moist gluten to obtain a product which is readily acceptable.

M. Heudebert (*manufacturer of health foods*): I, myself, manufacture a gluten bread for which a patent has been applied and for which I have obtained a German patent. You know, of course, that the German patent guarantees the character of the invention. I have succeeded in manufacturing a gluten bread without the addition of wheat flour but with the addition of a certain proportion of alimentary casein. This has permitted me to make a bread which contains only a very little starch (10 to 20 per cent.), and which is very agreeable to the taste.

Pharmacien Principal Pairault: Such a bread can not be called "gluten" because it contains something else.

M. Heudebert: When Professor Bouchardt wrote what the President read to us just now, the progress in this industry which has since been realized had not been made.

Dr. Chevalier: From the practical point of view, I demand that the amount of gluten be raised from 60 to 75 per cent. There are breads which contain 12.5 per cent. of starch, as I have shown you just now in the analysis which I read.

President: You know, gentlemen, that "Père Bouchardt," as he was called, was much interested in the question. He was a practical man. It seems to me that we might pay respect to his opinion when he tells us that gluten bread ought to contain 25 per cent. of wheat and 75 per cent. of gluten.

Dr. Chevalier: There has been progress since Bouchardt and we have not the right to make a work of Bouchardt which dates from 1880, the basis of a definition in 1909.

President: I merely gave the reference as information.

Pharmacien Principal Pairault: It is necessary to know if it may be admitted that gluten bread contains anything else but gluten and starch.

President: No, it ought to contain only gluten.

Dr. Chevalier: I propose that the maximum of 25 per cent. of carbohydrates and 75 per cent of gluten be accepted. You make patients pay very dear for gluten bread; they ought to get something for their money. In fancy breads, oatmeal breads, or breads made in the Vienna style, you have 62 per cent. of carbohydrates. You are going to have 40 per cent. in gluten bread. I think that the difference is not enough; 75 per cent. of gluten is necessary.

M. Arpin: Subtracting carbohydrates.

Dr. Chevalier: Yes, subtracting carbohydrates. I will change the question if you wish; I say that 60 per cent. of gluten is not enough to justify the name of gluten bread.

President: For the percentage of gluten ought we not to appeal to the Section on Hygiene?

Dr. Chevalier: I see no objection.

President: We are business men. We ought not to adopt rules which perhaps would not be applicable to all people in commerce.

M. Heudebert: I call your attention to what will happen from the commercial point of view. *The public is ignorant of all these questions.* [Italics ours.—Ed.] A bread is called antidiabetic; if it is sold at 50 centimes (10 cents) it will be bought by preference because it is cheap, without regard to the fact whether it contains starch or not. The manufacturer who succeeds in manufacturing a bread which answers the therapeutic requirements of Bouchardt will not be able to sell it cheap, because it will be composed of expensive material. He will then be at a disadvantage, whereas in all justice he will have furnished the solution to the question. In my opinion, one might enlarge the scope and give all possible liberty on condition that the buyer shall know that in buying a bread, whether cheap or dear, he has a product which does or does not answer to what the doctor has prescribed for him, and that he shall get his money's worth. There are antidiabetic breads which contain sugar.

President: We are discussing gluten bread, not antidiabetic bread. You will consider that in the Section on Hygiene. I put the question: Do you think that we, who are only merchants, can fix the minimum of gluten that ought to be found in gluten bread? Is not 60 per cent. a little large, and if we say 75 per cent., shall we not err in the other direction? It is not only specialists who make gluten bread; all bakers make it. Are we not going to expose all bakers to the danger of being prosecuted to-morrow if we demand 75 per cent. of gluten, because they will not all be capable of making a bread with that proportion?

M. Heudebert: Gluten bread is not bought as a luxury but as a necessity. That is the point of view to take.

President: That's therapeutics.

M. Bruzeau: From the point of view of defining frauds it is necessary to fix a minimum. The rest is therapeutics.

President: That's a sensible opinion from an independent person.

A Member: It seems to me that the question of gluten is not so important as that of carbohydrates. Why not indicate, as was proposed just now, a maximum of starch?

M. Arpin: I believe that the interests of the bakers would be better safeguarded by fixing a maximum of starch, because they would not easily succeed in making a bread which contains 75 per cent. of gluten.

President: The remark has been made to me that if you fix a maximum of starch it will be necessary to incorporate another ingredient.

M. Arpin: The minimum of gluten might be fixed likewise.

President: We should be doing bad services by trying to obtain the quintessence. Under pretext of repression of fraud, we ought not to declare conscientious people adulterators.

Dr. Chevalier: I do not speak as a commercial man. I am a physician. I say "You wish to make a definition of gluten bread, taking as a basis something which does not exist for diabetics. What you ought to give as a definition for diabetics is the maximum quantity of carbohydrates which ought to be contained in the bread. Patients do not need gluten, they need bread which does not contain carbohydrates."

Pharmacien Principal Pairault: Carbohydrates comprise starch, sugar, etc.

Dr. Chevalier: Starch or sugar or dextrin all become sugar in the stomach.

A Member: Should this question not be reserved for the Section on Hygiene?

M. Arpin: Almost all the bakers sell gluten bread. We need to discuss and to define it.

President: The question has been made the subject of study by the originators of the Congress. It has not been made a subject of special reports, but I know that M. Roux has a great deal of information and that M. Rocques, Rapporteur général, has probably not fixed the figure of 60 per cent. at random. We should do well to be tolerant and to adopt 60 per cent.

Dr. Chevalier: I think that 60 per cent. is too little, for the rest is composed of carbohydrates.

Pharmacien Principal Pairault: No, for there is water also.

Dr. Chevalier: Not at all, since we are figuring only the dry material. There is no water then.

President: The report says simply 60 per cent. of gluten.

Dr. Chevalier: There are gluten breads which have 5 to 10 per cent. of water, and others which have as much as 38 per cent.

Pharmacien Principal Pairault: It is understood that the gluten is all dry gluten but the report does not say dry gluten bread. One must take the bread as it is, so much gluten, so much starch, so much water. Consequently the 40 per cent. does not consist exclusively of carbohydrates: There is also 7 to 8 per cent. of water.

Dr. Chevalier: That depends on the manufacturer. Between 38 and 7 per cent. That is just why you cannot estimate on the basis of gluten bread; you must estimate it dry.

Pharmacien Principal Pairault: It is almost a hardtack.

Dr. Chevalier: There are gluten breads that contain more moisture than hardtack. That depends on the manufacturer.

Pharmacien Principal Pairault: A bread which contains 60 per cent. of gluten cannot contain 40 per cent. of carbohydrates.

Dr. Chevalier: This proportion of 60 per cent. can be understood only as calculated on the dry product. That is why it is necessary to define exactly and not say "60 per cent. of gluten" without knowing whether it is dry gluten and dry bread.

Pharmacien Principal Pairault: Let us say simply "containing a maximum of 20 to 25 per cent. of starch cereals without any other addition."

Dr. Chevalier: That is just what I demand.

A Member: We shall be sending the question to the pharmaceutic section next.

President: It is really more a question of pharmacy than of bakery.

Another definition is proposed: "Only breads containing 25 per cent. of wheat starch calculated on the basis of dry material ought to be called gluten bread."

A Member: But that is not gluten bread.

Pharmacien Principal Pairault: It is an antidiabetic bread, not a gluten bread.

M. Arpin: Yes, it is, the rest being gluten.

Pharmacien Principal Pairault: We ought to add "and not less than 60 per cent. of gluten."

M. Heudebert: That would not injure any baker at all.

President: I believe that this solution is satisfactory to everybody.

M. Arpin: It seems to me that all interests are safeguarded, even those of patients.

President: I am going to put to the vote the following definition of gluten bread:

"Only breads containing a maximum of 25 per cent. of wheat starch and a minimum of 60 per cent. of gluten, calculated on the basis of the dry material, should be called gluten bread."

This definition put to the vote was adopted.

Association News

THE LOS ANGELES SESSION

A Preliminary Statement Concerning Hotels and Hotel Rates

The reports which are coming in indicate that attendance at the next session of the American Medical Association will be large, and that geographical distance will not materially interfere with the attendance. The hotel facilities are ample, and the halls and hotel head-quarters are compactly grouped in the down-town district; and unless the weather records of years are changed, the weather during that week should be exceptionally good. The summer climate of Los Angeles is in every way as pleasant as the winter season.

The General Head-Quarters hotel will be the Hotel Alexandria.

The General Meeting of the Association will be at the Baptist Auditorium, at Fifth and Olive Streets.

Accompanying is a list of hotels and the rates which can be obtained at the time of the session, as reported to the Los Angeles Convention League. There are 400 family and tourist hotels and apartments available which are not included in the list. Those wishing to reserve rooms should write direct to the hotels, or to the Committee on Arrangements.

RATES AT LOS ANGELES HOTELS

As regards entertainment: the nearness to the ocean beaches and to the foot hills, with the trip to Catalina Island, and the possibility of out-of-door entertainments, will make possible a variety of features not easily had in other sections of the country.

We wish that those who are thinking of attending the session would drop a postal card to the Committee on Arrangements, 240 Bradbury Building, Los Angeles, Cal., stating the

"The Propaganda for Reform"

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION.

THE GLUTEN AND CARBOHYDRATE CONTENTS OF GLUTEN BREAD

At the Second International Congress for the Repression of Frauds, held in Paris, the proceedings of which are published by the Geneva White Cross Society, the question of the gluten and carbohydrate content of gluten bread was discussed. An abstract of this part of the society's proceedings, is given below, and the matter is further referred to editorially in this issue:

BREAD AND BAKERS' PRODUCTS

The following definition was proposed: "Gluten bread is bread made from a flour containing at least 60 per cent. gluten, this flour being obtained either by eliminating a part of the starch of the flour or by mixing a gluten flour with it."

Dr. Chevalier: The name gluten bread ought to be applied only to bread containing a maximum of 25 per cent. carbohydrates, starch, sugar or derivatives and 75 per cent. nitrogenous substances. According to Hewald, in fact, gluten bread ought to contain about 76 per cent of nitrogenous substances and 10 to 30 per cent. of carbohydrates. This means that in place of fixing a minimum of gluten or nitrogenous substances, one fixes a maximum of carbohydrates which is really more logical, for what the diabetic seeks is a food which is not a carbohydrate.

Pharmacien Principal Pairault: No doubt, but the question is very complicated.

The President: The definition of 60 per cent. of gluten is really the definition of the inventor of gluten bread, Bouchardt, who remarks that in his time a gluten bread was manufactured to which "legumine" was added, and which was sold under the name of "gluten and legumine bread."

M. Arpin: The definition is completed as follows: "In the above-mentioned breads the nitrogenous substances may be furnished by gluten, aleurone, casein, legumine, almonds, soya flour with oils removed, etc., but the presence or the association of these various substances ought to be specified." Consequently this would be an optional operation. That is another question which will come afterward. It is necessary first to complete the definition.

Dr. Chevalier: This quantity of gluten is not sufficient to justify the name of "gluten bread." Here are analyses published by M. Balland. He analyzed three gluten breads; they have the following compositions: The first two are very similar. They contain 36 per cent. nitrogenous substances; 1.25 and 1.76 per cent. of fat and 51.87 per cent. of starch for the first, and 52.92 per cent for the second. These are the commercial breads which exist at present. The third has the following composition:

Moisture	10.00 per cent.
Albuminoid nitrogenous substances	73.02 per cent.
Fat	3.45 per cent.
Starch	12.50 per cent.

It is evident that the first two breads cannot be considered gluten bread. There is nothing gained over a definition which is altogether therapeutic, and this is the point of view which I take. To give a patient gluten bread without any addition is not possible, but if you make bread with gluten and wheat flour you obtain too large a proportion of carbohydrates and therefore a bad bread. It is necessary to add either legumine or [illegible] substances containing a sufficiently large [illegible] to permit of the making of bread. [illegible] point of view, you ought to base the definition on the quantity of carbohydrates and not on the quantity of gluten.

Pharmacien Principal Pairault: Is it possible to manufacture bread with pure gluten? No! Then it must be admitted that there is a certain proportion of starch. What minimum proportion do you think possible from the practical point of view, from the bakers' point of view?

M. Arpin: Bread is made with pure gluten; I have seen it. But one needs to know if this bread can be easily masticated and digested by the diabetic.

Dr. Chevalier: From the practical point of view, I demand a maximum of 25 per cent of carbohydrates in gluten bread.

The President: This is what Bouchardt says in his book: "In the manufacture of gluten bread, the most conscientious manufacturers put in 25 per cent. of wheat flour and 75 per cent. of moist gluten to obtain a product which is readily acceptable.

M. Heudebert (manufacturer of health foods): I, myself, manufacture a gluten bread for which a patent has been applied and for which I have obtained a German patent. You know, of course, that the German patent guarantees the character of the invention. I have succeeded in manufacturing a gluten bread without the addition of wheat flour but with the addition of a certain proportion of alimentary casein. This has permitted me to make a bread which contains only a very little starch (10 to 20 per cent.), and which is very agreeable to the taste.

Pharmacien Principal Pairault: Such a bread can not be called "gluten" because it contains something else.

M. Heudebert: When Professor Bouchardt wrote what the President read to us just now, the progress in this industry which has since been realized had not been made.

Dr. Chevalier: From the practical point of view, I demand that the amount of gluten be raised from 60 to 75 per cent. There are breads which contain 12.5 per cent. of starch, as I have shown you just now in the analysis which I read.

President: You know, gentlemen, that "Père Bouchardt," as he was called, was much interested in the question. He was a practical man. It seems to me that we might pay respect to his opinion when he tells us that gluten bread ought to contain 25 per cent. of wheat and 75 per cent. of gluten.

Dr. Chevalier: There has been progress since Bouchardt and we have not the right to make a work of Bouchardt which dates from 1880, the basis of a definition in 1909.

President: I merely gave the reference as information.

Pharmacien Principal Pairault: It is necessary to know if it may be admitted that gluten bread contains anything else but gluten and starch.

President: No, it ought to contain only gluten.

Dr. Chevalier: I propose that the maximum of 25 per cent. of carbohydrates and 75 per cent of gluten be accepted. You make patients pay very dear for gluten bread; they ought to get something for their money. In fancy breads, oatmeal breads, or breads made in the Vienna style, you have 62 per cent. of carbohydrates. You are going to have 40 per cent. in gluten bread. I think that the difference is not enough; 75 per cent. of gluten is necessary.

M. Arpin: Subtracting carbohydrates.

Dr. Chevalier: Yes, subtracting carbohydrates. I will change the question if you wish; I say that 60 per cent. of gluten is not enough to justify the name of gluten bread.

President: For the percentage of gluten ought we not to appeal to the Section on Hygiene?

Dr. Chevalier: I see no objection.

President: We are business men. We ought not to adopt rules which perhaps would not be applicable to all people in commerce.

M. Heudebert: I call your attention to what will happen from the commercial point of view. *The public is ignorant of all these questions.* [Italics ours.—Ed.] A bread is called antidiabetic; if it is sold at 50 centimes (10 cents) it will be bought by preference because it is cheap, without regard to the fact whether it contains starch or not. The manufacturer who succeeds in manufacturing a bread which answers the therapeutic requirements of Bouchardt will not be able to sell it cheap, because it will be composed of expensive material. He will then be at a disadvantage, whereas in all justice he will have furnished the solution to the question. In my opinion, one might enlarge the scope and give all possible liberty on condition that the buyer shall know that in buying a bread, whether cheap or dear, he has a product which does or does not answer to what the doctor has prescribed for him, and that he shall get his money's worth. There are antidiabetic breads which contain sugar.

President: We are discussing gluten bread, not antidiabetic bread. You will consider that in the Section on Hygiene. I put the question: Do you think that we, who are only merchants, can fix the minimum of gluten that ought to be found in gluten bread? Is not 60 *per cent. a little large*, and if we say 75 per cent., shall we not err in the other direction? It is not only specialists who make gluten bread; all bakers make it. Are we not going to expose all bakers to the danger of being prosecuted to-morrow if we demand 75 per cent. of gluten, because they will not all be capable of making a bread with that proportion?

M. Heudebert: Gluten bread is not bought as a luxury but as a necessity. That is the point of view to take.

President: That's therapeutics.

M. Bruzeau: From the point of view of defining frauds it is necessary to fix a minimum. The rest is therapeutics.

President: That's a sensible opinion from an independent person.

A Member: It seems to me that the question of gluten is not so important as that of carbohydrates. Why not indicate, as was proposed just now, a maximum of starch?

M. Arpin: I believe that the interests of the bakers would be better safeguarded by fixing a maximum of starch, because they would not easily succeed in making a bread which contains 75 per cent. of gluten.

President: The remark has been made to me that if you fix a maximum of starch it will be necessary to incorporate another ingredient.

M. Arpin: The minimum of gluten might be fixed likewise.

President: We should be doing bad services by trying to obtain the quintessence. Under pretext of repression of fraud, we ought not to declare conscientious people adulterators.

Dr. Chevalier: I do not speak as a commercial man. I am a physician. I say "You wish to make a definition of gluten bread, taking as a basis something which does not exist for diabetics. What you ought to give as a definition for diabetics is the maximum quantity of carbohydrates which ought to be contained in the bread. Patients do not need gluten, they need bread which does not contain carbohydrates."

Pharmacien Principal Pairault: Carbohydrates comprise starch, sugar, etc.

Dr. Chevalier: Starch or sugar or dextrin all become sugar in the stomach.

A Member: Should this question not be reserved for the Section on Hygiene?

M. Arpin: Almost all the bakers sell gluten bread. We need to discuss and to define it.

President: The question has been made the subject of study by the originators of the Congress. It has not been made a subject of special reports, but I know that M. Roux has a great deal of information and that M. Rocques, Rapporteur général, has probably not fixed the figure of 60 per cent. at random. We should do well to be tolerant and to adopt 60 per cent.

Dr. Chevalier: I think that 60 per cent. is too little, for the rest is composed of carbohydrates.

Pharmacien Principal Pairault: No, for there is water also.

Dr. Chevalier: Not at all, since we are figuring only the dry material. There is no water then.

President: The report says simply 60 per cent. of gluten.

Dr. Chevalier: There are gluten breads which have 5 to 10 per cent. of water, and others which have as much as 38 per cent.

Pharmacien Principal Pairault: It is understood that the gluten is all dry gluten but the report does not say dry gluten bread. One must take the bread as it is, so much gluten, so much starch, so much water. Consequently the 40 per cent. does not consist exclusively of carbohydrates. There is also 7 to 8 per cent. of water.

Dr. Chevalier: That depends on the manufacturer. Between 38 and 7 per cent. That is just why you cannot estimate on the basis of gluten bread; you must estimate it dry.

Pharmacien Principal Pairault: It is almost a hardtack.

Dr. Chevalier: There are gluten breads that contain more moisture than hardtack. That depends on the manufacturer.

Pharmacien Principal Pairault: A bread which contains 60 per cent. of gluten cannot contain 40 per cent. of carbohydrates.

Dr. Chevalier: This proportion of 60 per cent. can be understood only as calculated on the dry product. That is why it is necessary to define exactly and not say "60 per cent. of gluten" without knowing whether it is dry gluten and dry bread.

Pharmacien Principal Pairault: Let us say simply "containing a maximum of 20 to 25 per cent. of starch cereals without any other addition."

Dr. Chevalier: That is just what I demand.

A Member: We shall be sending the question to the pharmaceutic section next.

President: It is really more a question of pharmacy than of bakery.

Another definition is proposed: "Only breads containing 25 per cent. of wheat starch calculated on the basis of dry material ought to be called gluten bread."

A Member: But that is not gluten bread.

Pharmacien Principal Pairault: It is an antidiabetic bread, not a gluten bread.

M. Arpin: Yes, it is, the rest being gluten.

Pharmacien Principal Pairault: We ought to add "and not less than 60 per cent. of gluten."

M. Heudebert: That would not injure any baker at all.

President: I believe that this solution is satisfactory to everybody.

M. Arpin: It seems to me that all interests are safeguarded, even those of patients.

President: I am going to put to the vote the following definition of gluten bread:

"Only breads containing a maximum of 25 per cent. of wheat starch and a minimum of 60 per cent. of gluten, calculated on the basis of the dry material, should be called gluten bread."

This definition put to the vote was adopted.

Association News

THE LOS ANGELES SESSION

A Preliminary Statement Concerning Hotels and Hotel Rates

The reports which are coming in indicate that attendance at the next session of the American Medical Association will be large, and that geographical distance will not materially interfere with the attendance. The hotel facilities are ample, and the halls and hotel head-quarters are compactly grouped in the down-town district; and unless the weather records of years are changed, the weather during that week should be exceptionally good. The summer climate of Los Angeles is in every way as pleasant as the winter season.

The General Head-Quarters hotel will be the Hotel Alexandria.

The General Meeting of the Association will be at the Baptist Auditorium, at Fifth and Olive Streets.

Accompanying is a list of hotels and the rates which can be obtained at the time of the session, as reported to the Los Angeles Convention League. There are 400 family and tourist hotels and apartments available which are not included in the list. Those wishing to reserve rooms should write direct to the hotels, or to the Committee on Arrangements.

Rates to Los Angeles

The Chairman of the Committee on Transportation wishes to state that he has received a great many letters from members inquiring about rates, routes, etc., to the Los Angeles session. He has been unable to answer them as yet for the reason that the railroads have not been able to agree on the rates. Notice has just been received that the western roads have made a rate of $62.50, round trip from Chicago to Los Angeles by any direct route, or by way of San Francisco. From St. Louis, Memphis and New Orleans the rate is $57.50; Missouri River Gateways (Omaha to Kansas City inclusive), $50.00; St. Paul and Minneapolis, $63.50. Dates of sale are June 5 and 6 and June 10 to 22, both inclusive. The final return limit is September 15. Additional rates will be published as soon as they have been announced by the railroads. Details of routes and the arbitrary amount to be added for the northern roads will also have to be announced later.

M. L. Harris, Chairman, Chicago,
Committee on Transportation and Place of Session.

Correspondence

Two Appendices in One Person

To the Editor:—In The Journal, January 21, Dr. W. G. Young writes of a case in which he found two appendices in one individual, each appendix being well-defined and well-developed.

Some years ago a patient was brought to me for operation for adhesions following an appendicitis operation. On opening the abdomen, I found an appendix about three inches long, containing two hard concretions, much to the surprise of another physician present, who stated that the year before he had stood by while the same patient was operated on in an acute attack, and had seen an appendix with three concretions removed. My explanation at the time was that probably the patient possessed an appendix six inches long originally, and the first operator had removed three inches with three concretions, the rest having escaped observation in the midst of acute inflammatory products. I do not know whether this was really the explanation, or whether the patient had two appendices, as the family physician still believes.

Robert T. Morris, New York.

A Theory of the Cause of Cancer

To the Editor:—In the quest for the cause of cancer, theory and speculation have run wild, but up to the present time we seem to be as far away from the goal as we were when the pathologist first began to unravel the almost hopeless tangle. Theories have been unnumbered, and among the more recent are those of the sturgeon's egg and the trout. Investigation has been directed to cancer in other kinds of fish. Maps have been prepared showing the relation of the so-called cancer areas to the natural distribution of trout.

Cancer does not seem to limit itself to those who dine on *hors d'ocuvres* and fish. It has occurred to me that possibly the commonest form of living animal cell which is ingested by human beings, and which might be the cause of new growth, is that of the fecundated hen's egg. The latter is practically unlimited in distribution, and, indeed, where it is not obtained, other varieties of immature ovular life are used in its stead; for instance, the egg of the common duck, the seagull, the ostrich and of many others, even of reptiles. To be sure, eggs are eaten, not always, but frequently, in the raw state as in egg-nog, beaten white of egg, and soft-boiled. In a lightly cooked egg, the ovum seems to resist coagulation more than the remainder of the egg.

We are told that all new growths are derived from one of the primitive layers, and in the fecundated egg we have all of these requirements—the endoderm, the mesoderm and the ectoderm. This living cell then, introduced into the human body and becoming attached to some abnormal part of the digestive apparatus, gastric, duodenal or intestinal ulcer for instance, begins its growth, and then by metastasis, its progress may become unlimited. In recent months laboratory work has been done in the artificial propagation of various cellular structures, notably that of the chicken embryo.

In The Journal (January 21, p. 198), Peyton Rous reports characteristic cancerous growths following the inoculation of small amounts of a watery filtrate of a chicken sarcoma, and also following inoculation of fluid supernatant after centrifugalization of a tumor emulsion.

If then, new growth may be transmitted, not necessarily by the intact living cell, the possible chance of transmission of new growth through the medium of its by-products becomes apparent.

Malcolm Seymour, M.D., Boston.

[Comment.—The theory that the germinal cells included in the hen's egg are the cause of cancer was proposed by G. Kelling in the *München. med. Wchnschr.*, 1904, li, No. 24. His communication was commented on editorially in The Journal, July 23, 1904, p. 269, and a second communication was made by him in the *München. med. Wchnschr.*, li, No. 43, 1904; abstr. in The Journal, Dec. 3, 1904, p. 1733. Kelling claimed to have produced malignant neoplasms by the inoculation of dogs with hens' eggs and also found that in human carcinoma of the stomach, a precipitin reaction for hen's-egg albumin could be obtained. This theory does not appear to have received any notice since that time. We have no known example of the successful transplantation or grafting of the cells of one animal species into the tissues or bodies of some other species; consequently it is rather far-fetched to assume that the living cells in the hen's egg might grow in the animal body.—Editor.]

Preservation of Rubber Bulbs

To the Editor:—Apropos of the note by Dr. Goodman, referring to the short life of rubber bulbs, in The Journal, Jan. 14, 1911, p. 113, and the letter on the same subject by Dr. Albert Robin, in The Journal, Feb. 4, 1911, p. 367, it occurs to me that it might be of general interest to note that the perishability of rubber bulbs, such as are used with sphygmomanometers, has been known for many years. Hill and Barnard, as early as 1897, employed a metal pump similar to that used for inflating bicycle tires on a sphygmomanometer devised by them, and reported it in the *Brit. Med. Jour.*, 1897, ii, 904.

Having encountered the same difficulty in my work with sphygmomanometers, I have had made pumps of two varieties which may now be obtained from instrument dealers at small cost. These pumps are small and are each fitted with a valve to prevent escape of pressure. The later model, which is smaller than the first, is also provided with a needle valve which permits the gradual release of pressure in the system. The first of these pumps has been in use for nearly two years, and from the number now extant, seem to be becoming increasingly popular.

Francis Ashley Faught, M.D., Philadelphia.

Differentiation of Chronic Nephritis and Neurasthenia.—Chronic nephritis with threatening uremia may sometimes present a group of symptoms in a neuropathic individual which might be mistaken for neurasthenia, e. g., headache, characterized by tightness and feeling of pressure, especially in the morning, giddiness, weariness and lassitude with inaptitude for mental or bodily work, diurnal somnolence, etc. An examination of the heart, the urine, the pulse and the retina will enable a diagnosis to be made.—F. W. Mott, in the *Practitioner.*

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DESCRIPTION OF SEPTIC TANK—HOW SOON AFTER CHILDBIRTH MAY CONCEPTION OCCUR?

To the Editor:—Kindly answer the following questions: 1. What is a septic tank? 2. How soon after the birth of a child may another conception take place? L., Ohio.

ANSWER.—1. A septic tank is a tank into which sewage is allowed to flow, there to remain for a certain time in order that solid matters may settle out and a certain amount of putrefaction occur from the action of the anarobic bacteria present in the sewage. Most of the benefit comes from the deposition of solid matter, which might otherwise clog filter beds. This solid matter is removed at intervals of some months. For fuller information see THE JOURNAL, Nov. 5, 1910, p. 1650, and Dec. 10, 1910, p. 2067.

2. Kroenig, in the *Zentralblatt für Gynäkologie*, 1893, page 445, describes a case of pregnancy in a secondi para who gave birth March 10, 1893, to her second child and July 4, 1892, to her first child. The first child was nursed ten days. A single coitus occurred four days after the birth of the first child, that is, on July 8. There was no further intercourse for three months. The second child, which was born 243 days after the fruitful coitus, was 52 cm. long and weighed nearly 8 pounds. This is the earliest recorded case of conception postpartum. It raises several interesting questions relating to the activities of the ovaries during pregnancy, the viability of spermatozoa in the lochia, the possibility of the nesting of the egg in the recently emptied uterus and the duration of pregnancy.

Weinberg, in the *Zeitschrift für Geburtshilfe und Gynäkologie*, vol. 1, page 7, in a paper on "The Effect of Nursing on Menstruation and Conception," has collected statistics which show that about 20 per cent. of nursing women and 80 per cent. of those who do not nurse menstruate within six weeks of labor. Of puerperæ who do not menstruate about one in one hundred become pregnant within six months and about six in ten of the puerperæ who menstruate become pregnant within the same period.

SILVER NITRATE AND OTHER COMMON GERMICIDES IN GONORRHEA

To the Editor:—Since reading the article on "Common Germicides" by Post and Nicoll, in THE JOURNAL, Nov. 5, 1910, I have often wondered why some of the more efficient germicides are not used clinically in the treatment of gonorrhea. I have not been able to find the information I want on the subject, nor have I been able to learn anything from a number of physicians with whom I have talked about the matter. Why can we not with advantage use tincture of green soap, alcohol or Senn's solution as an injection in gonorrhea? If we can, why has it not been done, and what is the proper way to use these agents? Why are argyrol and protargol used so extensively if silver nitrate is superior?
E. E. EVANS, M.D., Gary, Ind.

ANSWER.—Tincture of green soap and alcohol are both irritating to denuded epithelial surfaces; they cause hyperemia and increased weeping from the surfaces, and thus interfere with the formation of horny epithelium and healing. For these reasons, if for no other, they would hardly seem to be useful antiseptics in acute urethritis. The same reasons in less degree apply to Senn's iodin solution. As regards argyrol and protargol and silver nitrate: In the first place, of course, silver nitrate is fatherless and there is no one to tell every willing listener over and over again its wonderful qualities; in the second place, silver nitrate shares with alcohol the quality of being too irritating in efficient strength to be a satisfactory antiseptic for use in acute gonorrhea. In chronic gonorrhea, when properly used, it is unequaled by any of the newer silver preparations.

FINSEN LIGHT AND LUPUS VULGARIS

To the Editor:—Is the Finsen light much used in this country? What is the percentage of cures of lupus vulgaris by this method of treatment? Is lupus vulgaris more prevalent on the Continent of Europe and the British Isles than in the United States?
JOHN B. DONALDSON, Lorain, Ohio

ANSWER.—The Finsen light is now used very little in the United States; here and in Europe it has been largely replaced among dermatologists by the *x*-ray. The results in the Finsen Light Institute in Copenhagen for 456 patients treated up to Dec. 31, 1900, were as follows: In slight cases 83 per cent. of the patients were practically cured; in extensive cases 52 per cent. were practically cured; 130 patients were known to be well for five years. Lupus vulgaris is much more prevalent in continental Europe and in the British Isles than in the United States.

SURGERY ONE HUNDRED YEARS AGO

To the Editor:—I am informed that a history of surgery was published in THE JOURNAL some years ago and that it was afterward published in book form. If you have the book will you kindly send me a copy? If not, please inform me where I can obtain it. S. A. CLARK, South Bend, Ind.

ANSWER.—Perhaps the article you want is by Dr. George Fischer on "Surgery One Hundred Years Ago, a Historical Study," translated by Dr. Carl H. von Klein, Chicago. This work appeared in THE JOURNAL in 1897 in many issues, namely, from February 13 to August 14; also in the first part of 1898. It has not been published in any other form.

BLEPHAROSPASM A NASAL REFLEX

To the Editor:—Replying to the request of Dr. R. S. Lamb for information regarding "blepharospasm," I would refer him to the recent article on "Reflexes and Reflex Neuroses from the Upper Air Tract," by Dr. Bryant in the *Boston Medical and Surgical Journal*, Feb. 2, 1911.

Blepharospasm is usually a nasal reflex and the area involved is the tubercle of the septum and middle turbinal. In fact, this "*genital area*" of the nose is hyperesthetic and changes of blood-pressure induce the irritation which shows itself in the muscular movements. I have seen chronic symptoms, and, indeed, severe chorea, yield immediately to the removal of adenoids or to direct treatment of these areas within the nose; by direct I mean local applications under illumination. EDMUND D. SPEAR, M.D., Boston.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Feb. 11, 1911.

Gunckel, George I., D.S., sick leave of absence extended fourteen days.

Stone, Frank P., D.S., reported for duty at Presidio of Monterey, Cal.

Weed, Frank W., captain, reported for temporary duty at Madison Barracks; left Fort Totten, N. Y.

Trinder, John H., M.R.C., reported for temporary duty at Fort Totten, N. Y.

Lambie, John S., Jr.; Worthington, Joseph A.; Tasker, Arthur N.; Snyder, Howard M., and McKinney, Garfield L., first lieuts., ordered to report to Lieut.-Col. James D. Glennan, Medical Corps, president of examining board, Army General Hospital, San Francisco, for examination for promotion.

Foster, George B., Jr., lieut., relieved from duty at the Army Medical School, Washington, D. C., and ordered to Fort Leavenworth, Kan., for duty.

Bourke, James, captain, relieved from duty at Fort Leavenworth, Kan., and ordered to Fort Crockett, Texas, in time to arrive there about March 10, 1911.

Cowles, Calvin D., Jr., and Phillips, Hiram A., first lieuts., ordered to report to Lieut.-Col. Henry P. Birmingham, Medical Corps, president of the examining board, at the Army Medical Museum Building, Washington, D C., for examination for promotion.

Barber, John R.; Ashford, Mahlon; Huber, Edward G., and Hunt, William L., first lieuts., ordered to report to Major William E. Purviance, Medical Corps, president of the examining board, at Manila, P. I., for examination for promotion.

Schmitter, Ferdinand, captain, ordered to repair to this city for special duty in the laboratory at the Army Medical School for a period not to exceed seven days.

Moncrief, William H., captain, on arrival at San Francisco will proceed to Fort Riley, Kan., for duty.

Le Hardy, Julius C., M.R.C., directed to proceed from Manila, P. I., to San Francisco, March 15, instead of Feb. 15, 1911.

Bierbower, H. C., M.R.C., left Fort Robinson, Neb., en route to Fort Meade, S. Dak., for duty in field with 4th Cavalry.

Johnson, Howard H., captain, left Fort McDowell, Cal., on leave of absence to include Feb. 15, 1911.

Aydelotte, John T., lieut., left Fort Sam Houston, Texas, with troop F and H, 3d Cavalry, for duty in field at Marfa, Texas.

Fox, James S., lieut., ordered to duty with troop L, 3d Cavalry, in field at Samfordyce, Texas.

Austin, Thomas C.; Napier, Edward L., and Welles, Edward M., Jr., first lieuts., left Army General Hospital, San Francisco, for service in the field on Mexican border.

Kerr, James D., M.R.C., resignation accepted by the President, to take effect Feb. 7, 1911.

Johnson, Howard H., captain, leave of absence extended to and including Feb. 15, 1911.

Williams, Harry B., M.R.C., granted twenty-nine days' leave of absence.

Ireland, M. W., ordered to proceed to Chicago to attend the seventh annual conference on education and legislation of the American Medical Association to be held in that city March 1-3, 1911.

Pulver, Arthur L., M.R.C., granted leave of absence for one month and ten days.

Duncan, William A., captain, relieved from duty at Vancouver Barracks, Wash., and will repair to this city and report for duty at the Field Medical Supply Depot.

Medical Corps, U. S. Navy

Changes during the week ended Feb. 11, 1911.

George C. M., asst.-surgeon, ordered to duty at the naval hospital, Navy Yard, New York.

Sheldon, L., Jr., asst.-surgeon, ordered to duty at the naval hospital, Norfolk, Va.

Randall, J. A., P. A. surgeon, ordered to the naval station, New Orleans.

Ely, C. F., P. A. surgeon, ordered to temporary duty at the naval hospital, Naval Home, Philadelphia.

Brown, H. L., P. A. surgeon, ordered to the navy recruiting station, Los Angeles.

Munger, C. B., P. A. surgeon, detached from the navy recruiting station, Los Angeles, and ordered to the *Yorktown.*

Lumsden, G. P., medical inspector, transferred to the retired list from Feb. 7, 1911.

Haynes, J. P., P. A. surgeon, detached from the naval station, New Orleans, and ordered to the Asiatic station.

U. S. Public Health and Marine-Hospital Service

Changes for the seven days ended Feb. 8, 1911.

Anderson, J. F., P. A. surgeon, directed to proceed to lower Potomac river on special temporary duty.

Bahrenburg, L P H., P. A. surgeon, granted one day's leave of absence, Jan. 8, 1911, under paragraph 191, Service Regulations. *Granted thirteen days' leave of absence from Jan. 21, 1911, on* account of sickness.

Blount, B. B., A. A. surgeon, granted thirty days' leave of absence from Feb. 1, 1911.

Salmon, T. W., P. A. surgeon, granted two months and ten days' leave of absence from Feb. 8, 1911.

Sinclair, A. N., A. A. surgeon, granted one month's leave of absence, with pay, and four months and fifteen days, without pay, *from April 1, 1911.*

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

STATE LEGISLATION ON PUBLIC HEALTH

Since the progress of state legislation was summarized in The Journal, February 4, a number of additional bills have been reported. These are classified by states. The further progress of these bills will be reported in The Journal from time to time.

ARKANSAS

A bill has been introduced to provide for the punishment, by fine or imprisonment, of all those other than regularly licensed physicians who "by any verbal statement, writing, print, or other method, offer or profess to cure or treat any injury, disease or deformity of any human being by any drug, nostrum, manipulation or other expedient." The administration of domestic remedies is exempt, as are also midwives.

CALIFORNIA

A bill has been introduced to authorize the selection, by the state medical society, of 150 members as experts in various lines of medical knowledge, from which list seventy-five shall be selected by the board, acting with the attorney general of the state. This list is to be posted in the office of every county clerk for reference in all litigation or criminal cases. A bill has been introduced to provide that children attending schools may, in place of a vaccination certificate, file either a statement from the parent or guardian that he is conscientiously opposed to vaccination and will not consent to the vaccination of the child, or a certificate from a licensed physician to the effect that vaccination would seriously endanger the life or health of the child.

COLORADO

A bill providing for a state board of medical examiners of nine members has been introduced, also a bill creating an osteopathic board of examiners.

ILLINOIS

The following bills have been introduced in the Illinois legislature:

A bill to enable boards of education in cities over 100,000 to establish and maintain classes and schools for dependent, neglected and delinquent children; a bill to establish and maintain a home for widows, orphans and other dependents of persons losing their lives in hazardous occupations; a bill to regulate the practice of optometry (H. B. 121); a bill to provide for the inspection, licensing and regulation of cold storage warehouses (H. B. 123); a bill to amend the delinquent children law (H. B. 124); a bill to regulate the practice of optometry (S. B. 140); a bill for the prevention of cruelty to animals (H. B. 28); a bill to authorize the sterilization of habitual criminals, idiots, feeble-minded, and imbeciles (H. B. 49); a bill to amend the vital statistics law (H. B. 53); a bill to prohibit the establishing and enforcing the tuberculin test for dairy animals by any city or town (H. B. 55); a bill to amend the law regarding the suppression and prevention of contagious diseases among domestic animals (H. B. 56); a bill to provide for the establishment, erection and maintenance of sanitariums for tuberculous patients (H. B. 57); a bill to provide for the creation of public recreation districts (H. B. 73); a bill to provide for the establishment of a state sanitarium for persons afflicted with tuberculosis (S. B. 5); a bill to amend the law regarding marriages and to require a physician's certificate of health for a license to marry (S. B. 32); a bill to make an appropriation for the visitation and instruction of the adult blind (S. B. 74); a bill to forbid the issuing of policies insuring against accidental bodily injuries (S. B. 84).

The optometry bills introduced in the house and senate are similar to those previously introduced in Illinois and other states. The bill regulating the sterilization of habitual criminals and imbeciles is similar to the law adopted in Indiana and other states. Senate Bill 74, for the visitation and instruction of the adult blind, has been introduced at the request of the Chicago Women's Club. This bill would appropriate $20,000 for the use of the board of administration and provide for the visitation of the adult blind in their homes for the purpose of instructing them in industrial pursuits and helping to make them self-supporting.

INDIANA

The bill introduced by Senator McCarthy, providing for the medical inspection of school children, passed the senate by a vote of forty to one. The following bills have passed the house: H. B. 57 for the prevention of ophthalmia neonatorum; S. B. 57 to establish a Pasteur Institute.

The following bills have been introduced: A bill to amend the present medical practice act, introduced by Senator Stotsonburg, would give all graduates of approved medical colleges the right to practice without examination. The Board of Medical Registration, as well as the physicians of the state, is strenuously opposing this bill. A bill to amend the law regarding the operation of hospitals; a bill to require the medical inspection of all male applicants for a license to marry; a bill for the prevention of the transmission of venereal diseases, and a bill to regulate the sanitation and ventilation of steam and traction passenger cars and depots.

IOWA

Beside the osteopathic bill and the bill to create a health commission, which have previously been commented on, the following bills have been introduced: a bill to provide for the proper sanitation of barber shops; a bill to regulate cancer hospitals and sanitariums; a bill to regulate itinerant venders; a bill to require undertakers to report the names of persons dying of tuberculosis and to require the disinfection of premises occupied by infected persons and a bill to require physicians and osteopaths to report all cases of tuberculosis to the secretary of the State Board of Health.

MISSOURI

A bill to regulate the manufacture and sale of oleomargerine, a bill to provide for the medical examination of public school children, a bill to provide for a board of eclectic medical examiners (H. B. 52), and an optometry bill have been introduced. The house committee has reported unfavorably on the optometry bill.

NEBRASKA

A school medical inspection bill, endorsed by the Omaha Women's Club, has been introduced.

NEW HAMPSHIRE

An optometry bill (H. B. 40) has been introduced.

NORTH CAROLINA

A bill to permit physicians to register and practice on presentation of their diplomas, without obtaining a license from the State Board of Examiners, was introduced but has been reported on unfavorably by the house committee.

NORTH DAKOTA

The medical practice act introduced in the house, to place practitioners of all schools under the supervision of a single board, has passed the house and is now in the senate. A bill to provide for a board of control for all state educational, penal and charitable institutions has been introduced in the house.

OHIO

A bill to repeal the vaccination law, a bill to provide that no person suffering from tuberculosis shall be given a license to marry, and a bill to grant local boards of health the power to establish bureaus for the study of tuberculosis in their towns have been introduced.

OKLAHOMA

S. B. 70 would make all records of the State Board of Medical Examiners public records. S. B. 77 would amend the medical practice act, and S. B. 93 the State Board of Health act. S. B. 126 would preserve the purity of the waters of the state, including all streams and springs and all bodies of surface and impounded ground water, whether natural or artificial. Every municipality, private corporation, company, and individual supplying water to the public within the state would be required, within sixty days, to file with the secretary of the State Board of Health a certified copy of the plans of the water works and the source from which their water-supply is derived. All persons, corporations or municipalities supplying water for domestic purposes would have to secure a written permit from the State Board of Health.

OREGON

A bill to give the State Board of Health the powers of the state dairy and food commissioner has been indefinitely postponed. Bills to create a board for the examination of graduate nurses and to extend the powers of the State Board of Medical Examiners have been reported on favorably by the house.

TENNESSEE

A bill to incorporate laws regulating the practice of medicine, and making some amendments therein, has been introduced in both houses. This bill would provide that any person practicing or attempting to practice medicine under the name of any other person or firm would be guilty of a misdemeanor; would extend the term of members of the board from four to six years, and would make graduation from a medical college giving a four years' course a condition for license. A bill has been introduced to require a medical certificate as a condition for the issuing of marriage licenses.

UTAH

An amendment to the medical practice act has been introduced to make the attorney general an ex-officio member of the board and to make improper advertising and the performance of criminal abortions ground for revocation of licenses. An annual tax of $3.00 on all licensed physicians is also specified, the fund thus collected to be used by the State Board of Medical Examiners to prosecute violators of the law.

WASHINGTON

A bill to give the State Board of Health power to regulate traffic in oysters and other shell-fish has been introduced; a bill to amend the medical practice act, and a bill to provide for a commission to designate certain hospitals and surgeons in each locality who shall attend all injured persons and who shall be paid for their services from a fund furnished by the employer and employees. A bill to provide for a state tuberculosis sanitarium has been defeated. An amendment to the criminal abortion law has been introduced, to provide that women may testify without incriminating themselves.

WISCONSIN

An optometry bill has been introduced. Dr. C. A. Harper, the secretary of the State Board of Health, has introduced a bill to require the state health inspector to inspect hotels, jails, schoolhouses and public buildings, streets, alleys and other places; a bill to require cities to make adequate provision for the care of persons with advanced tuberculosis, and a bill for the prohibition of public drinking-cups in public buildings. An effort is being made to abolish the compulsory tuberculin test for cattle. A bill to provide for a more thorough system for the registration of deaths, a bill to prohibit the publication of the fact that a person has died of tuberculosis, and a bill to require a medical certificate before issuing a license to marry have also been introduced, as well as a bill to increase the tenure of office for health commissioners in cities, towns and villages, to four years.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Seventh Month—Third Weekly Meeting

INFECTIONS OCCURRING IN SURGICAL DISEASES AND CONDITIONS
SYMPTOMS OF TOXEMIA, SEPTICEMIA AND PYEMIA

TOXEMIA, SAPREMIA: History of local infection. Onset, fever, pulse, chills, gastrointestinal symptoms, headache, prostration, collapse. Blood-examination. Urine. "Typhoid" cases.

SEPTICEMIA: Intensity of symptoms, similarity to toxemia. Variations in symptoms due to different organisms. Blood changes. Clinical types: 1. Following local infection, gunshot wound, puerperium, trauma, etc. May be mild or severe. 2. Cryptogenetic septicemia; no history of previous infection. May be acute, subacute or chronic; may terminate in pyemia. 3. Due to mixed infection.

PYEMIA: Secondary to septicemia and toxemia. Difference in character and intensity of general symptoms. Symptoms indicating localization of metastatic abscesses; involvement of lung, pleura, cardiovascular system, brain, kidney, joints, eye, etc. Blood-examination. Course of pyemia, terminations.

TREATMENT

SEPTICO-PYEMIA OF VON LEUBE.

PROPHYLACTIC: Asepsis and antisepsis in prevention of infection.

SURGICAL: Removal of focus of infection. Prevent reinfection. Drainage of secondary infections. Production of artificial abscess.

SERUM-THERAPY: Antitoxic serums; bactericidal serums; serums raising resisting power of body or rendering bacteria more susceptible to phagocytes.

GENERAL: Elimination. Stimulation, alcohol, strychnin, quinin. Symptomatic treatment. Rectal or subcutaneous saline injections. Credé's colloidal silver injections.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

CONNECTICUT: Regular, City Hall, New Haven, March 14-15. Sec., Dr. Charles A Tuttle; Homeopathic, Grace Hospital, New Haven, March 14. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, March 14. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

ILLINOIS: Coliseum Annex, Chicago, March 2-4. Sec., Dr. James A. Egan, Springfield.

MAINE: Portland, March 14-15. Sec., Dr. F. W. Searle, 806 Congress Street.

MASSACHUSETTS: State House, Boston, March 14-16. Sec., Dr. Edwin B. Harvey, Room 159, State House.

WYOMING: Laramie, March 7-9. Sec., Dr. J. B. Tyrrell.

The Conference on Medical Education and Legislation

This joint conference will be held at Chicago, at the Congress Hotel—formerly the Annex—March 1, 2 and 3. On the first day will be held the Seventh Annual Conference of the Council on Medical Education at which, besides the reports of the chairman and secretary, will be the following addresses:

"Entrance Examinations," by Dr. Thomas S. Fiske, Secretary of the College Entrance Examination Board, New York City.

"Subjects Included in the 'Two Years of College Work' Required for Admission to Medical Colleges," by Dr. Charles R. Bardeen, Dean of the School of Medicine of the University of Wisconsin, Madison.

"A Five-Year Medical Course," by Dr. J. George Adami, Professor of Pathology, McGill University, Montreal.

"Equipment and Instruction of the Laboratory Years," by Dr. E. P. Lyon, Dean of St. Louis University School of Medicine, St. Louis, Mo.

"Equipment and Instruction of the Clinical Years," by Dr. George Blumer, Dean and Professor of Medicine of Yale Medical School, New Haven.

"The Educational Function of Hospitals," by Dr. Frank Billings, Dean of Rush Medical College, Chicago.

"Valuation of Credentials," by Dr. Frank B. Hiller, Secretary of the Missouri State Board of Health, Jefferson City.

"The State License Examination," by Dr. Horace G. Norton, Secretary of the New Jersey State Board of Medical Examiners, Trenton.

"Interstate Reciprocity," by Dr. W. T. Gott, Secretary of the Indiana Board of Medical Registration and Examination, Indianapolis

On Wednesday evening, March 1, a special session will be held at which the "State's Responsibility in Medical Education and Public Health Matters" will be discussed. The speakers for the evening and their topics are as follows:

"Standards and Authority"—George Edgar Vincent, Dean of the Faculties of Arts, Literature and Science of the University of Chicago, and President-Elect of the University of Minnesota.

"The Responsibility of State Universities in Public Health Matters"—William L. Bryan, President of Indiana University, Bloomington.

"Professional Education a Duty of the State"—Edmund J. James, President University of Illinois, Urbana, Ill.

A joint conference will be held on the second day to discuss medical practice acts. The following addresses will be given:

"The Importance of the Regulation of Medicine in the Administration of State and Municipal Governments"—Edward J. Brundage, Corporation Counsel, City of Chicago.

"The Attitude of the Judiciary in the Enforcement of Medical Practice Acts"—Judge Jesse A. Baldwin, Appellate Court, Chicago.

"Considerations Which Should Influence Appointments on State Examining Boards"—Hon. A. O. Eberhart, Governor of Minnesota.

"What Should Be the Attitude of the State Toward the Practice of Medicine?"—Dr. M. L. Harris, Chicago.

"Regulation of the Practice of Medicine for the Public Good"—Charles R. Henderson, Professor of Sociology, University of Chicago.

"The Administration of Medical Practice Acts."
  (a) "The Administrative Duties of the State Board of Medical Examiners"—Dr. A. B. Brown, Secretary of the State Board of Medical Examiners, Louisiana.
  (b) "Medical Prosecutions and Revocation of Licenses"—A. C. Umbreit, Attorney for the Wisconsin State Board of Medical Examiners, Milwaukee.
  (c) "The Defense of Medical Practice Acts in the Courts"—James N. Wilkerson, Attorney for the Texas State Board of Medical Examiners, Fort Worth.
  (d) "Financing of State Board Work"—Dr. Herbert Harlan, President Maryland State Board of Medical Examiners, Baltimore.

On the third day the Seventh Annual Conference on Medical Legislation will be held. Representatives and members of the National Legislative Council will present reports from the various states regarding the legislative situation in each. Separate reports will be presented by the committees on Carroll memorial, medical expert testimony, optometry, model medical practice, etc. Dr. Henry M. Bracken, secretary of the Minnesota State Board of Health will speak on "The Needs of Public Health Legislation." Dr. Cressy L. Wilbur, chairman, statistician of the Division of Vital Statistics of the Federal Census will speak on "The Progress of Vital Statistic Legislation." Legislative problems will be discussed and plans for the coming year will be outlined.

California December Report

Dr. Charles L. Tisdale, secretary of the Board of Medical Examiners of the State of California, reports the written examination held at Los Angeles, December 6-9, 1910. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75, and not less than 60 in any one branch. The total number of candidates examined was 95, of whom 60 passed, including 15 osteopaths, and 35 failed, including 13 osteopaths. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
University of Arkansas	(1908)	75.5
University of California	(1910)	83.2
University of Southern California (1906) 75.2; (1909) 87.1, 88; (1910) 84.4.

Book Notices

A MANUAL OF DISSECTION AND PRACTICAL ANATOMY OF HEAD AND NECK. For Students, Surgeons and Specialists. By Hubertus J. H. Hoeve, M.D., Professor of Anatomy in the Medical and Dental College of Drake University. Cloth. Price, $5. Pp. 598, with illustrations. H. J. H. Hoeve, Des Moines, Iowa, 1910.

In his preface the author says, "I came to the conclusion that the entire macroscopic anatomy for the dissecting-room and also for surgical purposes should be arranged in natural outline form, and consequently I have prepared this volume on the head and neck." The book contains 600 pages slightly smaller than those in Gray's "Anatomy," with the subject-matter arranged in typical outline form, with headings, subheadings and further divisions. As there is considerable descriptive text, and as the outline form is used in laying out the matter, the full space is occupied with this one region of the body. To put the "entire macroscopic anatomy" of a region such as has been selected into an outline, is a work that might appal one less hardy than the author. As to the real test of its merit the words of the author may be further quoted as follows: "To what extent I have failed in writing the much-talked-of and badly needed ideal dissector remains to be judged by my professional confrères."

The author is evidently an earnest advocate of the outline method with thoroughness in all its details. The extent to which this method expands the text is realized when we observe that two full pages are devoted to the omohyoid muscle and more than a page to the frontal artery and vein. Different casts of mind naturally vary the point of view, so that things are seen differently by different observers. So it is with outlines: while the frequent breaks in the description by the interpolation of headings, subheadings and other divisions disturbing consecutive reading are results naturally to be expected and willingly accepted in the usual synoptical treatment of a subject where the simple divisions amply suffice to suggest the rest of the matter under review, it becomes a matter about which there is much less likely to be a unanimity of opinion when besides this all the details are exhaustively filled in. Much that is valuable and difficult of access elsewhere is likely to remain hidden in the text on account of the tediousness of unraveling the outline.

The fifty-one half-tone illustrations are about equally divided between photographic reproductions and artists' sketches of original specimens. Although suggestive of interesting and instructive original specimens, the reproductions are not the best, and leave much to be desired. Thirty-nine of the illustrations are devoted to the brain, three to sections of the head, three to sections of the larynx and pharynx, three to sketches of the orbit, and one each to the mastoid region, the veins of the diploe, and the skull with relation to the ventricles of the brain. With due respect for the author's pride in presenting none but original illustrations, one cannot help noting the absence of the beautiful figures of dissected regions that are so characteristic of the usual works of this class, and which more than any other single feature serve to stimulate the student to neat and thorough work.

THE PHYSIOLOGY OF REPRODUCTION. By Francis H. A. Marshall, M.A., Fellow of Christ's College, Cambridge. With a Preface by Prof. E. A. Schäfer, F.R.S., and Contributions by William Cramer, Ph.D., and James Lochhead, M.D. Cloth. Price, $6. Pp. 706, with illustrations. New York: Longmans, Green & Co., 1910.

Marshall presents this subject in the most exhaustive treatise that has appeared for some time. The earlier chapter-heads in order are: "The Breeding Season," "The Estrous Cycle in the Mammalia," "The Changes that Occur in the Non-Pregnant Uterus During the Estrous Cycle," "Changes in the Ovary," "Spermatogenesis — Insemination," "Fertilization," "The Accessory Reproductive Organs," "The Biochemistry of the Sexual Organs," and "The Testicle and the Ovary as Organs of Internal Secretion." In this last-named chapter the author makes a most valuable contribution to the literature on the subject. He gives in detail the results of the experimental work of Brown-Séquard, Poehl, Zoth, Pregel, and Bouin and Ancel, Shattock and Seligmann, Boruttau, Ribbert, Carmichael and Marshall, Knauer, Halban, Morris, Glass, Dudley, Essen-Möller, Graefe, Flatau, Kleinhaus and Schenk, Dubreuil and Regaud, Lane-Claypon, Paton, Henderson, Soli, Fichera, Starling and many others. Summing up his fifty pages of review, Marshall says: "The fact that the testis is an organ of internal secretion seems now to be definitely proved. This secretion is probably formed throughout the entire reproductive period of an animal's life; but, in those animals which experience a periodic rut, it is no doubt at this season that the testicular hormone is produced in greatest abundance."

What the author said about the testes might with equal truth have been said about the ovaries. In fact, it may be taken as positively demonstrated that these glands through their internal secretion profoundly influence development throughout the reproductive period and especially during adolescence.

Other chapters in the book concern fetal nutrition and the changes in the maternal organism during pregnancy; the innervation of the female generative organs; lactation; fertility; the factors which determine sex. This last chapter, next to that on the internal secretion from the sex glands, will be of most interest to the practitioner, as Marshall devotes considerable space to the consideration of various theories with accumulated data and evidences pro and con.

The book is well illustrated; some of the illustrations are in colors, many of them new and all of them valuable.

While Marshall has covered ground frequently covered in the preliminary chapters of works on obstetrics or in the final chapters on physiologies, the survey is incomparably more complete than one will find in any of the works mentioned, and will be valued highly by those students of obstetrics who wish to familiarize themselves with the latest and best on this subject.

A MANUAL OF PHYSIOLOGY. With Practical Exercises. By G. N. Stewart, M.D., Professor of Experimental Medicine in Western Reserve University, Cleveland. Sixth Edition. Cloth. Price, $5 net. Pp. 1064, with 450 illustrations. New York: William Wood & Co., 1910.

The fact that this is the sixth edition is ample proof of the popularity of Stewart's "Physiology." And the fact that these six editions have appeared at intervals during fifteen years is proof of the book's worth; it has worn well. This edition is a little larger than the others, owing to the addition of new matter; but the volume is not too bulky to be held for comfortable reading.

Mention of the good qualities has been often made, and need not be here repeated; but one cannot refrain from commending the clear style that makes abstruse subjects, which easily become monotonously dull, plain and interesting. Sometimes an illustrative comparison strikes one as a little odd, such, for instance, as this concerning the heart: "Like a musical box devised to play a series of melodies in a fixed order, and from which a particular tune cannot be obtained till those preceding it have been run through, the heart in some way or other is arranged, in the presence of competing impulses from its extrinsic nerves, to play the tune of inhibition before the time of augmentation" (p. 146). Yet we would not have it changed, for the comparison is apt and the student will remember the fact because put in this striking way. There is a remarkably equable distribution of space allotted to different topics and an evenness of treatment that is too often missed in composite works by different writers. The details of experiments are plainly given. And there is a most admirable condensation without sacrifice of clearness and of needful detail which shows the hand of the investigator who at the same time can teach and explain. The author rarely permits himself to run into wearisome argument; there is almost nothing of the polemic. His own views on debatable questions are always definitely stated. Where no decision has as yet been reached this is frankly acknowledged. His judicial attitude is well brought out by his excellent discussion of the myogenic and neurogenic theories as to the heart-beat. While favoring the latter theory in many respects, he takes a neutral position, for on many of these points, he says, the proof is not yet convincing.

We wish that he had departed a little more from the original plan and had cited authorities a little more freely. Medical students would be incited often to consult originals if instead of being told that "it has been recently shown," they were given as well the author and reference. We realize the impossibility of loading up the pages with all the authorities consulted and the inadvisability, as well, of using such a mass of names; but a little breaking of the rule now and then, and the insertion of a bibliographic reference, especially when it concerns some classic article or some really worthy contribution, would make the work a still greater help to the student. As it is, this work is certainly one of the very best text-books on physiology for the undergraduate and a reliable reference-book for the practitioner.

Lehrbuch der Urologie, mit Einschluss der männlichen S[illegible]. Von Dr. Leopold Casper, Universitäts-[illegible] Paper. Price, 15 marks. Pp. 575, with 221 [illegible]: Urban and Schwarzenberg, 1910.

The first edition of Casper's well-known book has been translated into English. This, the second German edition, is an enlargement and improvement of the first edition.

The subject-matter is handled in two parts. In the general part is considered the anatomy, physiology and examination of the urogenital tract. The physical and chemical examination of the urine is given so briefly that the subjects could well have been omitted. Since the author has written a work on cystoscopy, it is but natural that he should treat that subject rather briefly here. The subject suffers, also, by being poorly illustrated. The chapter on urethroscopy would be more valuable if the illustrations were not so poor and if it included a consideration of the use of the Goldschmidt urethroscope. On the whole, the chapter on diseases of the urethra and penis is good; we must, however, differ from the author when he says that non-gonorrheic urethritis is very rare. We were surprised and disappointed to find no mention made of erosive or gangrenous balanitis, a disease which produces such fearful mutilations of the penis and which is surprisingly frequent when one is familiar with the clinical picture. The chapter on urethral stricture covers the subject satisfactorily and we are pleased to observe that the author condemns the operation of external urethrotomy except in selected cases.

Diseases of the bladder are covered fully, and lithotripsy is advised in preference to the more radical operation. Vaccine therapy in urology deserves rather more extensive consideration than it receives. The chapter on the kidneys would be improved by omitting the consideration of nephritis and enlarging on the subjects of nephrolithiasis and tumors. Since the author is a pioneer in the work, naturally a good deal of space is devoted to the functional diagnosis of renal affections. This should appeal especially to American surgeons, since this subject, until recently, has been somewhat neglected in this country.

The subject of tuberculosis of the genito-urinary system is well covered in the chapters devoted to the various organs. The author believes in the radical treatment of tuberculosis of the kidney. Probably the best chapter in the book is that on disease of the prostate, in which Young's operation for prostatectomy was given the preference.

Considering their frequency, the functional disturbances of the male sexual organs are considered somewhat too briefly.

Chronicles of Pharmacy. By A. C. Wootton. In two volumes. Vols. I and II. Cloth. Price, $6.50 net. Pp. 760, with illustrations. New York: The Macmillan Co., 1910.

These two volumes are filled with curious and interesting information, the result of an immense amount of painstaking labor. The history of pharmacy is traced from its mythical beginnings to the present time. Through a great part of this course it is almost identical with the history of medicine, although Wootton has paid special attention to the drugs mentioned by ancient writers. Following a chapter dealing with the myths of pharmacy, the author gives in succession what is known of pharmacy among the ancient Hebrews, Egyptians, Greeks and Romans. The story is traced through the Arabs to the middle ages, when the account becomes more definite and truly historical. An interesting chapter is the one devoted to the progress of pharmacy in Great Britain. Succeeding chapters deal with "Dogmas and Delusions," "Masters in Pharmacy," "Chemical Contributions," and other topics, such as "Poisons in History," "Noted Nostrums," etc.

The author has made an interesting and instructive book. His death before the publication of his work is deeply to be regretted. The volumes are attractively bound and illustrated by a considerable number of portraits and pictures of statues and other subjects related to pharmacy.

Cystoscopy as Adjuvant in Surgery. With an Atlas of Cystoscopic Views and Concomitant Text for Physicians and Students. By Staff-Surgeon Dr. O. Rumpel, Lecturer in Surgery at the University of Berlin. Only authorized English translation by P. W. Shedd, M.D., New York. Half leather. Price, $8.50. Pp. 131, with 107 illustrations. New York: Rebman Co., (1910).

The first fifty-nine pages of this book are devoted to the text, the subject being considered under "Congenital Anomalies," "Cystitis," "Tumors," "Hypertrophy of the Prostate," "Concretions and Foreign Bodies," and "Testing Renal Function." In the text are twenty-two illustrations. The text is rather brief and often simply explanatory of the plates which follow. The testing of renal function receives scant attention, and hence the chapter on that subject is quite unsatisfactory. Following the text are thirty-six plates in color, showing eighty-five views of various conditions found in the bladder. They are all, of course, cystoscopic views, and the outline and coloring are very good, but they are all pasted on the pages and at times without regard to "up" and "down" of the picture, so that they are often confusing in this particular. Opposite each plate is a description of the figures and frequently a short history of the case.

Hay Fever and Paroxysmal Sneezing (V[illegible] By Eugene S. Yonge, M.D., Physician to the [illegible] for Consumption and Diseases of the Throat. [illegible] Pp. 150, with illustrations. New York: William Wood & Co., 1910.

Under the title of "hay-fever" the author has described three separate conditions—hay-fever (hay-asthma), paroxysmal sneezing (vasomotor rhinitis) and idiopathic rhinorrhea (nasal hydrorrhea). The first he distinguishes by ascribing as its chief etiologic factor the pollen of plants: the second depends more largely on neuroses and pathologic conditions of the upper respiratory space: and the last he attributes to neurotic condition more largely, to chronic sinus diseases or to trauma. The constitutional states as predisposing factors overlap in the three conditions. The subject is treated historically and from the standpoint of the different theories and hypotheses. The frequent association of asthmatic symptoms is kept in view, but nothing is said about the theory of anaphylaxis as a factor. Not much that is new is advanced in the treatment. The work is an interesting review of the subject.

Diagnosis and Treatment of Diseases of Women. By Harry S. Crossen, M.D., Professor of Clinical Gynecology, Washington University. Second Edition. Cloth. Price, $6. Pp. 1025, with 744 illustrations. St. Louis: C. V. Mosby Co., 1910.

The second edition of this work has been considerably expanded in the text, and numerous original illustrations added, which further elucidate diagnostic methods. Among the subjects given added attention are pelvic inflammation and tubal pregnancy. The index has also been amplified, but laboratory methods, except in the instance of gonorrhea, are not included, a matter which was mentioned in our extended review of the first edition. Surgical treatment is still subordinated. The elaborate attention given to diagnosis, and to treatment other than surgical, makes this a good work for the student and general practitioner.

Die Faeces des Säuglings und des Kindes. Die Bedeutung und Technik ihrer Untersuchung. Von Dr. Adolf F. Hecht, Kinderarzt in Wien. Mit Einem Vorwort von Dr. Th. Escherich. Paper. Price, 8 marks. Pp. 186. Vienna: Urban & Schwarzenberg (American Agents, New York: Rebman Co.), 1910.

This volume is the result of seven years of careful observation and study of this important subject in Escherich's clinic in Vienna. The subject is treated exhaustively and the result is equally valuable as a book of reference for the pediatrician or the general practitioner, or as a guide to the investigator. The author is fortunately a clinician as well as a laboratory investigator. One can freely endorse Escherich's warm commendation of the book to any one who is interested in this increasingly important subject.

Differential-diagnostische Tabellen der inneren Krankheiten. Von J. Clemach, in Wien. Paper. Pp. 21. Price, 3 marks. Munich: J. F. Lehmans Verlag, 1910.

This little volume contains twenty-one tables in which the symptoms and physical findings of allied diseases are tabulated in parallel columns. It has the faults and merits inherent in all such treatises. The clinician finds the symptoms stated too arbitrarily and dogmatically to be of value. The student who must prepare for examination, however, will appreciate the condensed summaries and the convenient arrangement of the data.

Medicolegal

Liability for Professional Service, Board and Nursing for Wife at Hospital

The Second Appellate Division of the Supreme Court of New York in the case of Thrall Hospital vs. Cecelia T. Caren (124 N. Y. S., 1038) reverses a judgment rendered for the plaintiff, and grants a new trial. It says that the action was to recovery for board, nursing, etc., received by the defendant. It appeared that while her husband was sick in the hospital she was removed to it for an operation for appendicitis. Her attending physician made the arrangements for her admission to the hospital through a physician connected with the institution. She was too ill to make provision for herself, and did not. Indeed, her illness was so severe that the proposal to present a bill to her was postponed and the charges were not communicated to her until her departure, when she said she would send a check for them. Thereafter a bill for the amount was presented to her husband, then one was sent to her with a letter requesting payment, and this not receiving attention, a bill was later presented to the husband's estate. Thus the case was one where a woman, whose husband was in the hospital, and who was herself too ill to contract, was received by it pursuant to arrangements made by the physician in attendance cooperating with a physician connected with the hospital, and on discharge promised to send a check for the bill, which was presented to her husband and to his estate, and intermediate such two presentations to herself, without attention by her. She did not engage the physician, so far as appeared. She did not promise to pay before the service was rendered. Did the law imply a promise? The answer is:

The defendant seemed to have had a home. Her physician advised her that she should go to the hospital, and made the arrangement through a physician connected with the hospital. A physician's service is a necessity that should be furnished by the husband, and presumptively was in this case, either through himself, or her implied authority to call a physician to attend a member of the family. The physician so acting for the husband advised her to go to the hospital, and she went accordingly. So the professional service was necessarily rendered in the hospital, and for it the husband was primarily liable. The board and nursing were incidental to such service. It might be that the husband elsewhere supplied a home and sustenance for her; but the room, board and attendance at the hospital were for a different purpose and inseparable from her treatment. In this view the plaintiff, thoroughly informed, should have regarded the husband as its debtor, unless the defendant expressly engaged the service, and thereby became personally liable. But there was not the slightest evidence that she did or was able to do that. Indeed, the plaintiff carefully refrained from broaching the subject until the time of her departure, when the defendant promised to send a check. Such statement did not cast the obligation on her. A wife does not become the principal debtor, or surety for her husband's debt, by promising to send a check for it, even if her own check is indicated.

Duties of Carriers to Sick Passengers and When Not Liable for Unusual Pain

The Supreme Court of Georgia says, in Central of Georgia Railway Co. vs. Madden (69 S. E. R., 165), that it is not one of the ordinary undertakings of a carrier of passengers to furnish nurses or medical attention. This idea has been expressed by saying that the carrier does not conduct a hospital. If one who is sick, with knowledge of the fact, gets aboard a train, he cannot complain that he suffers pain because of such sickness, or that the ordinary and necessary motion of the train increases his pain, without negligence on the part of the carrier; or that he lacks medical attention or nursing, with which he has not provided himself, and which the carrier has not agreed to provide for him. Nevertheless, a carrier of passengers does not deal with the strong and well and the vigorous alone; and a condition may arise by reason of the sickness of a passenger on its trains which will create an emergency imposing on the carrier the duty of dealing with the passenger in accordance with the situation thus arising.

If it should be ascertained that a passenger was suffering with small-pox, the carrier not only might cause him to leave the train before arriving at the destination pointed out in his ticket, but, under its duty for the protection of its other passengers, it might become necessary to compel him to do so. So, also, if a passenger should have a ticket for a journey of 1,000 miles, and after he had been carried 100 miles it should be ascertained by the conductor of the train that such a passenger was in a dying condition, it could hardly be successfully urged that the agents of the carrier could wholly ignore this situation and allow the man to die, without opportunity for obtaining assistance or attention, merely because he had not reached the destination pointed out in his ticket. It will thus be seen that circumstances and emergencies may raise a duty on the part of the carrier to afford a passenger a reasonable opportunity to leave the train and to obtain assistance before reaching the destination originally intended.

So if a passenger on a railway train becomes ill in transit, and this is known to the servants of the carrier in charge of such train, or is so apparent that they are charged with knowledge of it, it is their duty to give him or her such care and protection beyond that demanded under ordinary circumstances as is reasonably practicable with the facilities at hand and consistent with the safe and proper conduct of the business and the safety and comfort of the other passengers.

More particularly, the court holds here that where a female plaintiff contended, and introduced evidence tending to prove, that she became ill while on board a passenger train, and that the carrier was negligent in failing, on request, to afford her opportunity to leave the train in order to procure assistance and medical attention, and in failing to assist her in leaving it after knowledge of her condition, but that she succeeded in getting off, though suffering extreme pain and about to be delivered of a child, it was not error to refuse to charge the jury that, if they believed she was able to leave the train without the assistance of the conductor, she would not be entitled to recover damages.

But it was error to charge that "the defendant would not in any event be responsible for such pain as she (the plaintiff) would have suffered on account of the birth of a child. For pains incident to childbirth, if no more, if not unusual pain, you should find for the defendant." That implied a necessary right to recover for unusual pain; but the mere fact that a woman under such circumstances may have suffered more than usual pain would not entitle her to recover damages. If there could be a recovery, it must be for that which resulted from a want of due care on the part of the carrier or its agents, while there may have been a premature delivery, and unusual pain, caused by the ordinary motion of the train, without negligence or liability on the part of the defendant.

NORTH CENTRAL SECTION OF THE AMERICAN UROLOGICAL ASSOCIATION

Meeting held in Chicago, Jan. 5, 1911

Dr. R. H. Herbst, President of the Chicago Urological Society, in the Chair

Position Drainage in Suprapubic Prostatectomy

Dr. Henry J. Scherck, St. Louis: The principal objection to the ordinary form of drainage, either siphon or suction, is that it does not completely empty the bladder of decomposed or septic urine, and allows it to become absorbed in a freshly wounded bladder and space of Retzius. The abdominal position does not allow the septic material to remain in contact with these surfaces, and this minimizes the chances of absorption.

DISCUSSION

Dr. L. W. Bremerman, Chicago: I can drain the bladder suprapubically or perineally by automatic interrupted siphonage. During the first twenty-four hours following suprapubic prostatectomy the bladder can be emptied every five minutes, keeping it dry and keeping the dressing on the abdomen practically dry and making the patient comfortable.

Dr. Gustav Kolischer, Chicago: The prone position was used in various conditions years ago, and in spite of it, many patients developed hypostatic pneumonia. The real dangers following suprapubic prostatectomy or any suprapubic operation are postoperative hemorrhage and infection around the bladder.

Dr. E. G. Mark, Kansas City: The things to look after following suprapubic operation of any kind are hemorrhage, infection or infiltration into the abdominal wall or perivesical tissues, and hypostatic pneumonia. I am convinced that position has a great deal to do with the development of hypostatic pneumonia.

Dr. R. B. F. Gradwohl, St. Louis: The method of drainage described by Dr. Scherck is admirable in respect to the prevention of hypostatic pneumonia.

Dr. Arthur Dean Bevan, Chicago: I take a tube about the size of the index finger, measuring it accurately, so that it will project ¾ of an inch into the bladder, then I take a fine catgut suture and introduce it into the suprapubic wound, stitching both above and below the tube. It almost invariably requires but a single suture above and a single suture below the tube. This suture passes through, first, the bladder wall, and second, takes a good bite of the tube and goes through the opposite wall, and is then tied. In the space between the bladder and symphysis we tuck in a small cigarette drain with iodoform gauze, projecting beyond the gutta percha.

Genital Tuberculosis

Dr. F. W. Robbins, Detroit: In only two of twenty cases of genital tuberculosis was it possible to trace a relationship between tuberculous epididymitis and a previous gonorrhea. In neither of these patients was the tubercle bacillus found, and the diagnosis of tuberculosis may well be questioned. Rarely does genital tuberculosis follow venereal disease. About 60 per cent. of cases of genital tuberculosis are a part of the general tuberculous infection. Occasionally the disease may be so located in the external genitals as to make radical operation wise, but more often the disease of the external organ is associated with that of the prostate and vesicles, even when the bladder and kidneys are healthy. It is seldom good practice to do the extensive operation recently described by Whiteside.

DISCUSSION

Dr. Hugh Cabot, Boston: I have never seen a case which occurred in such a way as to suggest that gonorrhea was the cause of the subsequent tuberculosis.

Dr. D. N. Eisendrath, Chicago: In two cases I saw there was a direct relation between gonorrhea and tuberculosis In both cases a preceding gonorrhea had seemingly furnished the ground for the localization of the tubercle bacillus. One patient had a greenish discharge containing gonococci, and enlargement of both epididymes. The other patient had an abscess which ruptured through the scrotum. Gonococci were found in the pus. I advised antigonorrheal treatment, and it was instituted for two months without benefit. We examined the pus discharge for tubercle bacilli and found a large number of them. The whole course lasted about a year. The patient died from uremia. Autopsy showed extensive tuberculosis, a mixed infection where we had removed the epididymis, and in the kidneys, also showing gonococci, tubercle bacilli in the kidneys, pus, and a stone in the kidney.

Dr. R. H. Herbst, Chicago: A man had a large nodule in the upper pole of the epididymis, the size of an English walnut, in the region of the external ring, and painful, two nodules in the prostate, had frequency of urination. He was put on tuberculin. The nodule at the external ring and the nodules in the prostate disappeared, as well as the frequency of urination, one week after treatment. He still has a small nodule in the upper pole of the epididymis. Tuberculin, if used properly, is valuable, and should be used in almost every case.

Dr. G. Frank Lydston, Chicago: It is not an easy matter to prove the association between gonorrheal infection and genital tuberculosis. A large majority of cases of genital tuberculosis have been preceded by gonorrhea. If it is true that gonorrheal infection reduces resistance and does not predispose to tuberculosis, then we have a rule that differs from all other rules with reference to tuberculosis. An individual with a lowering of the power of resistance in the mucosa, other things being equal, is particularly susceptible to infection by the tubercle bacillus. The chief argument against the relation of gonorrhea to tuberculosis of the urogenital tract was missed altogether by the opponents of that theory, and that is that infection, as a rule, is descending, coming from the kidney, and from the substance of the kidney rather than from the pelvis, excepting secondarily. Gonorrheal infection of the kidney is relatively exceptional, as contrasted with the sum total of cases of gonorrhea.

A Case of Air Embolus Occurring During Operation Under Air-Inflation Urethroscopy

Dr. Ernest G. Mark, Kansas City, Mo., read a paper with the above title. It was published in The Journal, Feb. 11, 1911, page 419.

Local Paresis of the Urinary Bladder

Dr. Gustav Kolischer and Dr. Harry Kraus, Chicago: Certain cases of paresis of the bladder are caused by edema of the bladder wall. This edema may be produced by gross mechanical interference with the circulation by the impaction of tumors, or by inflammatory changes in the adjacent organs. That the bladder is paretic is shown by the fact that catheterization alone does not lead to a satisfactory emptying of the bladder, but that outside pressure has to be resorted to in order to express all the urine. That the edema of the detrusor is the cause of the vesical paresis is proved (1) by the cystoscopic findings; (2) by the palpatory findings after the bladder was drained; (3) that there are no disturbances of the central nervous system to be found; (4) that this bladder paresis disappears without any special treatment after the factors that interfere with the circulation are removed.

The Caput Epididymis an Excretory Organ

Dr. William T. Belfield, Chicago: The head of the epididymis is a part of the middle kidney, which functionates as a kidney in frogs and fishes, but is superseded in man by the permanent kidney. The efferent tubules constituting the head of the epididymis are the convoluted tubules of this early kidney. That they are secretory organs is indicated by the motion exhibited on traversing these tubules by the previously motionless spermatozoa. Their excretory function is indicated by the infection of these tubules with various organisms derived from the blood, e. g., those of tuberculosis, syphilis, typhoid, and the colon bacilli. These infections may extend along the genital tract to the prostatic urethra. Until recently, all infections of the kidney were assumed to ascend from the bladder. It is now known that many infections of the bladder descend from the kidney. Similarly we have been accustomed to regard all infections of the genital duct as *ascending* from the deep urethra; but must realize that in certain cases these infections begin in the convoluted tubules (head) of the epididymis and *descend* to the vesicles and deep urethra, there being a complete analogy between the second kidney (caput epididymis) and its duct on the one hand, and the third (permanent) kidney and its duct on the other. Hence, to limit treatment of all genital duct infections to the prostate and vesicles is as irrational as to limit treatment of all urinary infections to the bladder.

Other papers read were "Diagnosis in Advanced Cases of Renal Tuberculosis," by Dr. H. Cabot, Boston; "Salvarsan in Syphilis," by Dr. C. Wagner, Chicago; "Operation Cystoscope," by Dr. W. N. Senn, Chicago.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

Medical Record, New York

February 4

1 *Electrocardiograms and Their Significance. T. E. Satterthwaite, New York.
2 *Use of Electricity in Chronic Disorders of the Stomach. L. H. Levy, New Haven, Conn., and J. G. Wells, New York.
3 Direct Transfusion. F. D. Gray, New York.
4 *Percussion of the Kidneys. O. Lerch, New Orleans.
5 Keratitis Ex Acne Rosacea. W. B. Weidler, New York.
6 Recognition and Treatment of Gonorrheal Urethritis and Cystitis in Women. W. E. Dannreuther, New York.
7 Clinical Value of Blood-Pressure Studies. F. A. Faught, Philadelphia.

1. **Electrocardiograms.**—The Einthoven electrocardiographic machine is described by Satterthwaite. He says that the sensational statements which have appeared in the public journals as to the utility of the instrument must be received with much caution. The electrocardiogram does not as yet of itself distinguish uniformly functional from organic heart diseases; neither can the instrument dispense with the personal examination of the patient. Hence, a complete diagnosis cannot be made by the instrument when the patient and the physician are far apart. Strictly speaking, Einthoven has not inaugurated a new method; he has utilized the photographic method of Marey, and the string galvanometer of Ader, while the credit of the completed instrument is due to Edelmann. Einthoven has, however, given close study to the method with the perfected instrument, and he is, therefore, entitled, more than any other man, to have electrocardiography associated with his name. The instrument is capable of showing the time and force of action of ventricles and auricles; notes lack of transmission; and demonstrates ventricular and auricular extrasystoles more clearly than any other method. It is certainly useful in various forms of arhythmias, particularly when there is more or less complete auriculo-ventricular dissociation. At present, however, the initial cost of the Einthoven machine, and the expense connected with operating and maintaining it, will be a bar to its general use, except in the larger hospitals or research laboratories.

2. **Electricity in Chronic Disorders of the Stomach.**—Levy and Wells advocate the use of electricity in treatment of most chronic diseases of the stomach, which have not responded to the regular medicinal methods of treatment and diet.

4. **Percussion of the Kidneys.**—Lerch uses the drop stroke in percussion instead of the hammer stroke. He uses an ivory pleximeter and a hammer with rubber-covered head. By the drop stroke he eliminates the personal factor in percussion and gets more accurate results. He can map out accurately any of the internal organs by this method. The kidneys may be mapped out in the normal position and when displaced. The author has studied his method on the cadaver, and states that one may determine by it whether both kidneys are affected in Bright's disease, and the increase in bulk of the organs.

16 A New Tonsil Knife. O. A. Lothrop, Boston.

8. **Reflexes in Surgical Diagnosis.**—Morris claims that many cases of neuralgia, treated medically, belong distinctly in the surgical class. Lumbago, or neuralgia of the sciatic nerve, often is due to an enlarged prostate gland, distended seminal vesicles, pelvic adhesions and to septic or mechanical disturbance of the uterus and adnexa. Cases of trigeminal neuralgia are commonly treated on medical diagnosis alone, and patients often say that they have not even been questioned, by neurologists of standing, relative to peripheral irritations. Morris recently operated on a patient who had suffered intensely from trigeminal neuralgia, and who had been given alcohol injections by a most competent surgeon interested in that subject, but who had not examined the pelvis at all. So intense was the woman's suffering, that at the time of the last alcohol injection, she prepared a fatal dose of morphin in a glass of water to be taken just before her anesthesia. She wished to commit suicide but to avoid disgrace to the family by having it appear that she had died from the influence of the anesthetic. The reason why she did not take the dose was that at the last moment the anesthetist refused to allow her the glass of water. When she came under Morris' care, a little later, and a large ovarian cyst was removed, the neuralgia disappeared promptly, excepting for an occasional twinge of the supra-orbital nerve at times when the barometer is low. In this case the ovarian cyst was the precipitating factor in a patient, no doubt, predisposed to trigeminal neuralgia. In another case, a woman had suffered terribly from "neurology" as she put it. In this case, Morris excised a portion of the inferior dental nerve, giving relief for about a year. On the return of the neuralgia, he sent her to a competent ophthalmologist to determine if eyestrain could be a peripheral factor in the case. The neuralgia was apparently cured permanently by correction of eye muscle imbalance.

10. **Reflexes and Reflex Neuroses from the Upper Air Tract.**—Bryant shows that the reflexes and reflex neuroses emanating from the pharynx in number and significance are second only to those arising from the nose.

11. **Reflex Disturbances Referable to the Ear.**—A plug of impacted cerumen, says Page, has been known to produce, through its irritation of the external auditory canal, its interference with the pressure equilibrium of the middle ear, and, consequently, that of the labyrinth, nearly every known reflex disturbance, even suicidal mania.

14. **Intravenous Use of Cocain.**—The subject of experiment during the past three years, three times had local anesthesia produced with cocain—once of a finger, once for work on teeth, once because of a boil on the back of the neck. The analgesia produced at these times was not different in character or duration from that usually seen. There had been no other use of cocain or allied drugs. This experiment was performed as follows: Into one of the superficial veins of the back of the hand there were slowly introduced 5 grains of cocain in a 2 per cent. solution. The introduction of the solution was completed in about thirty minutes. Dizziness and palpitation made it seem wise to stop with this amount. Tests of the patient's condition were made at once and results were found to correspond in an incomplete way with those reported for animals. Cerebration was normal, except for a restless inability to keep the mind long on one subject. Motor power was unimpaired. There was marked analgesia everywhere. An incision ¾ of an inch long through the skin, well down into the fat, was made on the anterior surface of the lower leg. This incision could be felt; it caused a mere trifle of pain. Two or three small nerves in the fat were cut; each caused a slight twinge of pain. Apparently operative procedure might readily have been undertaken with only very moderate discomfort. Two hours later a similar central incision was made on the opposite side. The sensation of pain had by this time recovered much but not all of its normal intensity. It would seem evident, then, that however suited to animals this method may be, the relatively enormous dose necessary for even an imperfect result makes it impossible for human surgery. (This experiment is of peculiar value, since the experiment was performed by the writer on himself.)

18. **Diet in Typhoid.**—When milk disagrees, when there is abdominal distention, and when curds appear in the stools, Nammack's favorite formula is milk, 4 ounces; fresh cream, 1 ounce: lime water, 1 ounce. This is given every three hours, and is followed by a mixture of dilute hydrochloric acid, 10 minims in 1 dram of a reliable essence of pepsin. To this prescription, strychnin is added when required. Between each two portions of milk, albumin water, made by adding the white of 1 egg to 6 ounces of boiled water, is given. The patient is also solicited to drink plain water freely. If there is complete intolerance or aversion to milk, then buttermilk or kumyss or kefir can frequently be borne. There is no danger, in Nammack's opinion, in forcing this quantity of fluid through the cardiovascular apparatus and the kidneys, unless acute nephritis exists as a complication In that case it is both useless and injurious to attempt to drive this quantity of liquid through an inflamed and partly impermeable kidney filter. The quantity and quality of the daily urine output must be carefully studied, and attempts at flushing the kidneys postponed, until the mechanical obstacles to the flow of urine are removed. After the third week, Nammack usually allows crackers with butter, well-cooked rice, calves-foot jelly, and broth, and other solid foods when the evening temperature reaches normal. Of twenty-eight patients treated according to this plan, twenty-seven recovered; one died from ulcerative endocarditis; three patients recovered after severe intestinal hemorrhages, and in one small boy perforating appendicitis developed in the fourth week, but he recovered, after operation, performed within four hours after the onset of the appendicitis.

21. **American Relapsing Fever.**—This case occurred in the Panama Canal Zone and was typical in every respect.

30 *A Satisfactory Method of [illegible] Bladder. F. E. Fee, Cincinnati.

30. **Suprapubic Drainage of the Bladder.**—The apparatus used by Fee consists of a 1 or 2-gallon bottle and a 1-quart bottle, equipped in the following manner: The large bottle is to be filled with water, and must have two openings, one at the ordinary neck and one at the bottom, both closed with rubber stoppers, each containing a perforation for a small tube. The lower tube is connected with a short drainage tube, passing below to a waste jar, and on this tube near the bottle is placed a small screw clamp to regulate the outflow drop. Two inches below this is placed a glass bulb dropper of the same variety as used in the Murphy proctoclysis apparatus. This bulb conveniently shows the rapidity of the outflow drop. From the neck of the bottle a small drainage tube is connected with a 1-quart bottle, the neck of which is closed with a rubber stopper containing two openings, one of which is connected with the large bottle, and the second opening is connected directly with a tube leading to the patient. The tube should have two short observation glasses inserted, one near the bottle and the other near the patient. Fee prefers to have a large drainage tube, ½ inch in diameter, inserted into the bladder, and through this a No. 10 catheter is passed, directly connected with the drainage apparatus. The lower end of the large drainage tube should have several holes cut in its side to facilitate the passage of urine into it. The tube passing into the quart bottle should only extend down about 2 inches. The one passing to the large bottle should extend into the neck about 1 inch. This permits the urine to drop into a small bottle and not be aspirated into a larger one. If this apparatus is to work satisfactorily, the catheter and tubes should be cleansed as often as necessary, depending on the condition of the urine; and, should it be thick and flow slowly, frequent cleansing is necessary. When all the connections are properly made, and little or no air is allowed to enter the tubes, the discharge drop need not exceed 150 drops per minute, and the large bottle need not be filled with water but twice in twenty-four hours. Fee says that with the exception of a slight wetting of the dressings, caused by the presence of the gauze drainage, for the first two or three days, this apparatus will satisfactorily drain practically all the urine from the bladder and deposit it in the small bottle, from which it can be drawn every twelve hours, measured and examined.

44 *Carbo-Gasoline Method for Disinfection of Books. W. L. Beebe, Saint Cloud, Minn.

37. Abstracted in The Journal, Sept. 17, 1910, p. 1044.

43. **Effect of Vacuum Desiccation on the Virus of Rabies.**—The authors found that by using Shackell's method of desiccation, the essential feature of which is that the material is kept solidly frozen during the process of drying, brains and cords may be desiccated *in toto* without destruction of virulence. The time required for the complete extraction of water is from twenty-four to thirty-six hours. A number of brains have been so treated and the infectivity of all has been preserved. After the completion of desiccation, these brains were placed in an ordinary desiccating jar over sulphuric acid and left continually exposed to light at the ordinary room temperature. One brain has remained infective for four months. The only precaution taken was to guard against moisture. Material thus dried is like chalk and is easily pulverized. It is, however, very hygroscopic and, after a few hours' exposure to the air, becomes leathery and rapidly loses its infectivity.

44. **Carbo-Gasoline Method for the Disinfection of Books.**—The difficulties that prevent the disinfection of books seem to be numerous. If a gaseous disinfectant is used, it is very hard to have it penetrate all parts. Steam injures the book to some extent. An ideal method, therefore, would seem to be to use a liquid that would not be injurious and still kill all the pathogenic organisms that frequently infect them. Beebe found that gasoline does not injure books even after they are soaked in it for two or three hours if they are quickly dried. Gasoline has the advantage of dissolving fats and oils and, theoretically, it would appear that if a germicide were added it would act on bacteria in a dry and perhaps a wet medium. Several disinfectants which were soluble in gasoline were tried, but phenol was the only one that seemed to be efficient. In testing the efficiency of carbo-gasoline it was necessary to devise a special technic. A very volatile gasoline, which is termed 88 Baume or gas machine gasoline, was used. Liquefied phenol crystals were added to the gasoline in different amounts, and the disinfecting properties tested on several organisms. A 1 per cent. solution was sufficient to kill all non-spore producing organisms in less than five minutes. Some books were disinfected by this method after first infect-

ing them with several different organisms. In all cases 88 Baume gasoline, containing 2 per cent. phenol, was used. The books were opened at the pages where they were to be infected, put in the autoclave and sterilized at 15 lbs. steam pressure for fifteen minutes. They were then infected with *B. typhosus*, *B. coli communis* and *B. diphtheriæ*. They were left in carbo-gasoline for twenty minutes. One of the books was dried over night in a sterile chamber before cultures were made. In all, sixty-two inoculations were made, eighteen with *B. diphtheriæ*, nineteen with *B. typhosus*; eighteen with *B. coli communis* and seven with *Staphylococcus pyogenes aureus*, without growth in any case. Books that were treated by this method were not injured, unless the cover was lettered with an oil paint. In such cases, if care be taken not to touch the letters before the books are dried, no harm is done. This method has been tried on several different bindings, such as leather, cloth and paper, and in no case has the binding been affected. Gasoline of a lower specific gravity than 88 Baume can be used, but it takes longer for the gasoline to evaporate. If the odor of phenol and gasoline is offensive, oil of peppermint, wintergreen or cinnamon can be used as a deodorant. Beebe has found oil of peppermint, 3 parts; oil of wintergreen, 1 part, and oil of cinnamon, 1 part, efficient in disguising the odor of phenol.

52. **Physiologic Studies of Anaphylaxis.**—Schultz found that single intravenous or intraperitoneal injections of horse serum seem to have no effect on the normal irritability of intestinal muscle toward the same serum provided the muscle be tested within a period of one or two hours after the injection. If, after the first injection of foreign serum, a long enough interval elapse, intestinal muscle shows a supranormal degree of irritability toward the same serum. The time necessary to acquire this increased irritability is probably coincident with that required for the process known as sensitization in anaphylactic animals. Guinea-pigs may be rendered tolerant to large doses of foreign serum by injecting increasingly large doses of it, at intervals of two days, for a period of twenty to thirty days. The gross body reflexes and the cardiac and respiratory reactions differ markedly from those of a sensitized animal, but intestinal smooth muscle continues to show a supranormal irritability toward a serum similar to that of smooth muscle from a sensitized animal. The tolerance induced by repeated injections of foreign serum resembles tolerance acquired toward certain chemical substances familiar to pharmacologists. As to immunity, it seems impossible by repeated injections to initiate a condition of absolute immunity, since certain tissues not only remain irritable to the serum but acquire a supranormal irritability to it.

53. **Action of Ether on Anaerobic Animal Tissue.**—Mathews tested the action of ether on the nerve cord of the heart of the king crab, *Limulus*. The experiments consisted in separating the nerve cord from the posterior part of the heart, leaving it attached only to the front segment of the long, tubular heart. The hydrogen was generated by pure zinc and sulphuric acid and the gas was well washed in alkalin and acid permanganate, sodium hydrate and water. The replacement of air by hydrogen generally stimulated slightly both the rate and amplitude of the contractions. The contractions slowly diminished in the course of an hour in hydrogen from a rate of seventeen to a rate of about ten a minute. If air was then readmitted the rate usually fell still lower. Substitution of the ether-hydrogen mixture for hydrogen caused a short preliminary increase in the rate and amplitude of the contractions and increase in the tone of the heart-segment, provided the ganglion was in good condition and had not previously been anesthetized. This preliminary stimulation did not occur, or lasted only for two or three beats if the ganglion had been anesthetized once or twice before. Further action of the ether in all cases caused a cessation of contractions. When the ether was washed out with a stream of hydrogen, the ganglion was markedly stimulated on recovery. The ganglion generally recovered fully in the hydrogen. The recovery in the hydrogen was in most cases as prompt and complete as it apparently would have been in air; in a few cases, however, after being first for a considerable period in the hydrogen, the recovery from ether was very slow in the hydrogen, but rapid on changing the air. These results show, therefore, that the actions of ether on this facultative anaerobic tissue, while undergoing anaerobic respiration, is in all respects essentially the same as the action of ether on other aerobic nervous tissues, and as the action of ether on the same tissue in the presence of air, i. e., primary stimulation, followed by inhibition and after-stimulation on recovery.

56. **Relation of the Phosphatids to Narcosis.**—Koch and McLean doubt that there is any evidence that anesthetics or hypnotics produce changes in the state of aggregation of lecithin or kephalin, which are sufficiently consistent to account for such a general phenomenon as narcosis. They found some evidence, however, that chloroform as distinguished from pure ether has the power to form a combination with lecithin, a phenomenon which may be brought into relation with its slow elimination and consequent tendency to produce delayed poisoning.

66. **Disturbance of Sensation in Syringomyelia.**—In the case cited by Allen, the pathologic process completely isolated the posterior columns from the rest of the spinal cord from the first cervical to the eleventh thoracic segments, inclusive. There was perfect preservation of tactile sensibility and loss of pain and temperature sensibility. There was very diagrammatically demonstrated the lower limit of the trigeminal area. The cavity formation in the gliomatous tissue was most marked on the right side. Allen says that the case demonstrates the following facts: (1) The pathway for tactile sensations lies in the posterior columns; (2) with total cutting off of all the afferent pathways of the spinal cord with the exception of the posterior columns tactile sensation is not in the least impaired; (3) the validity of Mann's hypothesis is not questioned by the findings of this case.

71. **Immunity in Tuberculosis.**—Webb and Williams report on an animal which was inoculated weekly for nine months with a tubercle culture, from which 150 bacilli had been found to infect a guinea-pig. The inoculations were all made subcutaneously around the region of the navel. Autopsy failed to show any evidence of tuberculosis. The authors believe, therefore, that it may safely be considered that a guinea-pig has received, without the production of tuberculosis, about 1,000 times a lethal quantity of living virulent tubercle bacilli.

72. **Examination of Cattle for Tubercle Bacilli.**—The microscopic examination of the feces or rectal scrapings of cattle for tubercle bacilli was found by Reichel and Deubler to be of no value in that many bacteria make their appearance in the feces or rectal scrapings with the morphology and staining characteristics of tubercle bacilli, which, however, fail to prove themselves as such. Of the forty cattle included in the examination, nine (22.5 per cent.) were found to be throwing off virulent tubercle bacilli in the feces or rectal scrapings. Of these nine cattle, the tubercle bacilli were found virulent for guinea-pigs, and in eight of the nine the tubercle bacilli were virulent for rabbits. The authors believe that the successful demonstration of tubercle bacilli in the feces or rectal scrapings of cattle is either proof that extensive or "open" lesions of tuberculosis exist, or an indication that tubercle bacilli ingested are passing through the length of the alimentary canal of the animal under examination. Cattle, with "open" lesions of tuberculosis, and throwing off tubercle bacilli in the feces or rectal scrapings, as a rule show physical symptoms of the disease. Cattle showing physical symptoms of tuberculosis are the most active disseminators of the disease, because of the probable existence of "open" lesions, and the likelihood that tubercle bacilli are thrown off in the excreta. Since they show physical symptoms they may be detected in a herd by a consideration of the history, careful observation and a thorough examination of each animal. Tuberculin-reacting cattle do not necessarily throw off tubercle bacilli in the feces until the development of "open" lesions of tuberculosis, in which event the condition may be detected by a consideration of the history, careful observation and a complete physical examination.

73. **Volume Index of Red Corpuscles.**—Larrabee believes that the method of estimating the volume index by spontaneous sedimentation, while perhaps less accurate than the centrifugal method, is good enough for clinical uses. Normally, the corpuscles settle to about 50 per cent. of their total volume, where their number per cubic millimeter is 5,000,000. A volume index from 0.9 to 1.10 may be considered normal. Healthy persons occasionally show considerable variations beyond these limits. Concentration does not of itself affect the volume index. In pernicious anemia the volume index is almost invariably raised. The serum often has a distinct yellow color. The high index is probably also to be expected in those cases in which the pernicious picture is associated with other diseases, that is, when pernicious anemia occurs secondarily. In secondary anemia the volume index is almost always normal or lower than normal. After a severe hemorrhage, however, the volume index and the color index may be high and the blood may resemble pernicious anemia in other respects. One patient with aplastic anemia examined by Larrabee showed a low volume index. In a case of splenectomy for trauma the index was normal. In leukemia the volume index can seldom be estimated by this method. In splenic anemia the volume index was generally low. It was below normal in one case of Hodgkin's disease and high in one of malignant lymphoma.

74. **Osteitis Deformans.**—The case cited by Higbee and Ellis presented essentially all the features of the disease described by Paget, the most common manifestations of the affection being pronounced. The patient died and a careful and thorough postmortem examination was made, both macroscopic and microscopic. The findings were typical of the disease.

75. **Experimental Chronic Nephritis.**—The method used by Mitchell was very similar to that of Ophüls. Two per cent. potassium bichromate was injected subcutaneously. The amount used was started at 1 c.c. weekly, but was gradually increased in order to overcome the recuperative power mentioned by Ophüls. In one rabbit, 1/50 grain of atropin was administered simultaneously with the potassium bichromate. There was in a rabbit, injected only twice, a very marked parenchymatous nephritis with little or no indications of interstitial change. When the injections were continued several months, the predominating lesion was an interstitial nephritis. There is no evidence to show that this was produced at the same time as the parenchymatous lesion or following it. The feature noted especially in these experiments was the exophthalmos in one rabbit, which, to Mitchell's knowledge, has not been noted in experimental chronic nephritis or other conditions produced by chronic systemic intoxication. That the exophthalmos did depend on such an intoxication is, he thinks, the most probable explanation. There was no appreciable effect from the atropin used in one rabbit.

76. **Histology of Hypernephromata.**—Wilson and Willis studied fifty-four renal tumors, forty-eight of which were so-called hypernephromata; twenty-six swine embryos (serial sections), 5 to 20 millimeters; forty-three human embryos (serial sections), 6 to 70 millimeters. They concluded that most, if not all, so-called adrenal rests are probably of Wolffian origin. There is almost no evidence, embryologic or histologic, in support of Grawitz's hypothesis that the so-called hypernephromata have their origin in adrenal rests. There is much evidence that the so-called hypernephromata do not arise from proliferations of the adult secreting epithelium of the convoluted tubules. There is much evidence that the hypernephromata do arise from islands of nephrogenic tissue. Such tissue is sometimes present in the adult kidney and appears capable of forming tumors of the non-infiltrating, mixed-cordon, tubular, papilliform, and sarcoma type so characteristic of the so-called hypernephromata.

77. **Erythrocytic Nuclei of Normal Human Blood.**—King believes that he has been able to demonstrate conclusively that practically every red blood-cell in the blood of normal adults contains stainable remnants of a nucleus, and that the red blood-cells are derived from the bone marrow erythroblasts by a process of physiologic nuclear degeneration, accompanied, of course, by other changes. That the basic staining material which can be shown to exist in the central portion of practically every erythrocyte is nuclear material, King sees no reason to doubt. He feels almost confident that in a single preparation he has seen as many as ten ruptured red blood-cells, from each of which from two to six blood-platelets were emerging. He says he can hardly escape the conclusion that the blood platelets are simply the extruded fragments of the erythrocytic nuclei. The method by which he has been able to demonstrate the nucleation of the red blood-cells is simple and easily carried out. A solution of poly-

chromatic methylen blue is essential, also a saturated solution of picric acid in distilled water. This solution should contain an excess of the picric acid. In addition to these, a 1 per cent. aqueous solution of eosin, and a modified Romanowsky staining fluid will be needed. The blood films should be made on perfectly clean slides in the usual way. They must be neither too thick nor too thin. A little experience will be required before the best results can be obtained. The film should be immediately fixed for two or three minutes in methyl alcohol, and the following steps taken: (1) Rinse in tap water; (2) place for ten minutes in the blue solution; (3) rinse in water; (4) place for ten minutes in the picric-acid solution; (5) rinse in water; (6) place in 1 per cent. eosin solution for from one-half minute to two minutes; (7) rinse in water, and blot perfectly dry; (8) stain for five minutes with King's modified Romanowsky staining fluid; (9) rinse in water; dry, and examine with oil immersion.

79. **Investigations of Pulmonary Tuberculosis.**—The investigations made by Caulfield and others embrace: Variations in the type of v. Pirquet tuberculin reaction; deflection of complement test; procedures outlining possible classifications based on demonstrable serum reactions, and opsonic and phagocytic estimations. Two hundred patients were studied. Briefly, the data obtained from the procedures reported have given a means of grouping certain of the otherwise more or less indefinite clinical conceptions afforded by any study on a number of cases of pulmonary tuberculosis. Until certain of the reactions are proved specific Caulfield thinks it is doubtful whether the different end-results do or do not represent specific conditions between the host and the tubercle bacillus. Regarding the results in the light of clinical work and not from the standpoint of specificity the various data have aided definite conception on three considerations of tuberculous infection: (1) the existing relation between the infecting tubercle and host, as evidenced by (2) the amount of anatomic involvement and (3) the resulting clinical responses. The temporary prognostic values apparently afforded by the interpretation of the type of tuberculin reaction, of antigen-serum reaction, and of the phagocytic behavior of the patient, have been followed chiefly under the favorable circumstances of sanatorium life where most patients exhibit their best powers of resistance. In obtaining these results, observations were made which suggest that the biologic classification might change with clinical variation. Especially was this so with regard to the reactions obtained with various strengths of antigen and patient's serum. Here conception and expression are facilitated by regarding the possibility of two serum contents or reaction capacities. (1) Inhibition.—Serums with this effect allow hemolyses on the addition of "system" because of their serum-antigen resultants which are repellant or non-attractive to complement. (2) Tuberculous sensitizers:—Serums with these specific bodies cause true fixation of complement, shown as complete absence of hemolysis.

80. **The Swamp Fever of Horses.**—Swamp fever is a disease of horses which is widely distributed in the Western United States and in Western Canada. It is usually a chronic disease and is characterized by emaciation, weakness, irregular temperature and anemia. It is caused by an infecting agent which can be transmitted from horse to horse by the inoculation of blood taken from an infected animal. All search for a parasite by Todd and Wolbach, which might cause the disease, has been unsuccessful, although large numbers of preparations of body fluids and tissues have been examined at all stages of the disease by microscopic and bacteriologic methods.

88. **Renal Activity.**—Brodie's view is that the glomerulus is, in reality, a means by which there may be set up at the commencement of the tubule a pressure-head sufficient in magnitude to drive the fluid down the tubule. The renal tubule is a long structure possessing an extremely narrow lumen. If, then, we apply Poisseuille's law governing the flow of fluid along capillary tubes to the kidney tubule, we at once see that a considerable pressure is required to drive even a small volume of fluid along such a tubule. It is a well-established fact that the watery part of the urine arises mainly, even under certain circumstances, entirely at the glomerular surface, and this fluid is discharged down the tubule. If we could measure the length of the tubule, the diameter of its lumen in its various sections, and then determine the volume of urine flowing along the tubule in a given time, we could, assuming that Poisseuille's law holds for the tubule, determine how great a pressure is required to maintain such a flow. To test the view, Brodie made some experiments of the following type: A vigorous diuresis was set up in an anesthetized dog by the injection of a warm, saline solution. The rate at which the urine was discharged from one kidney at the height of this diuresis was then determined, and immediately the renal vessels and ureter were ligatured and the intact organ which thus contained, as far as possible, the whole of its blood and urine at the instant of ligature, was fixed in formalin. After hardening, it was cut into portions, the medulla separated from the cortex, and pieces of the cortex weighed, embedded, and cut into sections. These were mounted in series, and then the total number of conglomeri in the whole kidney was calculated from the ratio of the weight of the whole cortex to that of the small piece examined.

The lumen of the tubule in its various parts was next measured. Taking one experiment as typical, Brodie found that a pressure of as much as 93 mm. of mercury was required to drive the fluid along one of the tubules at the rate observed during the experiment. The question at once arises: Whence is this pressure-head derived? There are only two possible sources: (1) a secretory pressure set up by the cells in some part of the tubule, presumably at the glomerulus, since the secretion of water is effected there, or (2) a direct pressure transmitted through the glomerular surface from the blood-pressure. All attempts made to ascertain whether any of the cells of the renal tubule can set up a secretory pressure analogous to that observed in the case of the submaxillary gland, have completely failed. The maximum pressure at which urine can be discharged from the kidney is always from 30 to 40 mm. Hg less than the arterial blood-pressure. Hence, Brodie's suggestion is that the pressure-head is derived from the capillary blood-pressure within the glomerulus, that pressure being transmitted in undiminished amount through the glomerular capillary wall and epithelium. To express this view of the hydrodynamic action of the glomerulus, he terms the glomerulus a "propulsor."

89. **Chronic Rheumatism.**—The whole argument made by McCrae is that there is no entity which we can properly term "chronic rheumatism," and he tries to point out the reasons for doing away with one of the names which is so often treated. He says that the public often reproaches physicians for the inability of the profession to cure "chronic rheumatism." Is it any wonder, he asks, when in so many instances the actual condition is not properly diagnosed but is given a name which does not have any reference to it, and to this the treatment is directed; witness the patient with popliteal aneurysm, on whom much good medicine has been wasted. We can still echo the hundred year old sentiment of Haygarth that a number of conditions are grouped together as rheumatism, which have no other feature in common than the occurrence of pain.

92. **Diagnosis of Tuberculosis.**—Thomson emphasizes (1) the lymphatic nature of the disease in its primary state; (2) the predisposition of the paravertebral cranial parts of the lung; (3) the rarity of single lesions in the lower lobes or bases of the lungs; and (4) the importance of percussion. He also notes the value of the v. Pirquet test in all questionable cases. He regards it as an undoubted advance over the uncomfortable subcutaneous injection with its accompanying fever.

98. **Phylogenetic Association.**—It is the purpose of the authors to offer evidence that, underlying medicine, there are certain great natural laws which show that disease as well as health is a part of the web of life; that every phenomenon of disease fits precisely into a general plan, and that like a difficult picture puzzle if we persist we can make up the completed picture of disease. The experimental work and the laboratory findings are described fully, but the length of the article and the limited space in these columns, unfortunately prohibits abstracting this paper.

107 *A Successful Case of Cartilage Transplantation for Prevention of Perforation in Submucous Resection. I. D. Kerr, Boston.

107. **Cartilage Transplantation for Prevention of Perforation in Submucous Resection.**—In Kerr's case there was a marked cartilaginous deviation to the right with a corresponding large basal spur. There was considerable crusting and secretion in the nares. The mucous membranes bled easily, and on both sides of the septum a small white area of cartilage denuded of its mucous membrane was seen. It seemed to the author that if she did a submucous resection these traumatic perforations in the mucous membranes, together with the incision on one side anteriorly, although apparently not directly opposite when the deviated cartilage had been removed and the subsequent shrinking of the mucous membrane had taken place, that a perforation would result. To prevent this, it occurred to her that she might try transplanting a piece of cartilage between the perforations. With this thought in mind, she removed only enough cartilage with the Ballenger knife to allow space to remove the basal spur. That done, she removed the anterior half of the deviated cartilage above, and found a sufficiently straight and large enough remaining piece of cartilage to transplant, and this she allowed to remain in position until she had completed the operation. She then transplanted this piece of cartilage, which was about three-quarters of an inch in length and about one-half inch in width, bringing it as far forward as the incision. The flaps of the incision were brought carefully into place and the nares packed for twenty-four hours. Three days after the operation granulations were seen springing in from the edges of the perforations of the mucous membranes. In ten days the granulations had completely filled in, and no cartilaginous areas could be seen. Seven months have now elapsed since the operation. There is no perforation, the mucous membrane presents a healthy condition, there has been no epistaxis, and the patient, a girl, has perfect breathing.

5 Myasthenia with Enlargement of the Thymus. J. O. Symes.
6 *Antihemolytic Action of Arsenic. J. A. Gunn and W. J. Feltham.

2. **Treatment of Pulmonary Tuberculosis.**—While there is nothing new in Bosanquet's paper his emphasis of the principles of the treatment of tuberculosis is worthy of repetition. He says that there is no specific remedy or universal mode of treatment for tuberculosis of the lungs. Neither tuberculin, nor rest, nor work, nor mountain air, nor a sea voyage, nor a sanatorium, is an infallible remedy to be administered to all, as we give quinin for malaria or mercury for syphilis. We must study the individual patient, his circumstances and his idiosyncrasies and, armed with this knowledge, try to raise his resistance to the bacillus and its poisons. Fortunately, the human organism has considerable powers of resistance, if it is not debilitated by adverse conditions; and though we must, above all, endeavor to recognize cases early, before the disease has advanced far, yet even in advanced cases there is always hope of arrest of the disease or at least of a temporary reprieve and prolongation of life.

3. **One Thousand Inoculations.**—The anterior surface of the thigh is the least painful, and in any patient who is at all needle-shy, Crowe always injects in this region, varying each time the exact locality. Other situations are into the extensor surface of the upper arm, the deltoid, or into the skin of the abdomen, but he has usually avoided the conventional site, namely, that of the intrascapular region, as the skin is so tough that it is extremely difficult to avoid hurting the patient. Sometimes he gives the injection deeply into the muscles, sometimes subcutaneously, but he does not believe

the result is affected. The vaccines he used have all been home-grown, with the exception of acne and tuberculin. Of thirty-two cases of staphylococcus infections, twenty-eight patients were cured. One case of pyemia terminated fatally; two patients with acne and one with suppurative eczema are still under treatment. Three of four cases of streptococcus infections yielded readily to the treatment. *In one case* of nasal catarrh, apparently caused by an extremely long streptococcus, no dose had any effect whatever. The case was a complete failure under treatment. Of six cases of infection due to *B. coli communis*, four patients recovered; one patient with nephritis and one with mucous colitis were not benefited. In seven cases of infections of the respiratory passages other than tuberculous, and caused by the pneumococcus, *M. catarrhalis*, bacillus of Friedländer, and the bacillus of influenza, the patients responded promptly. In a case of unresolved pneumonia, due to Friedländer's bacillus, the whole condition cleared up within forty-eight hours after the first inoculation, although the man had been in bed for a fortnight with high temperature, and extreme dyspnea on the slightest movement. Of thirty-six cases of tuberculosis (skin, one; kidney, two; peritoneum, three; glands, four; breast, one; bones, five; lungs, twenty;) seventeen patients were *cured* (lungs, seven; bones, breast and skin, one case of each; glands, four; peritoneum, three); five patients were benefited (bones, one; kidney, one; lungs, three); *eight remained unaffected* (kidney, one; bones, two; lungs, five).

4. **Typhoid Infection.**—Rats are suggested by Mills as being carriers of typhoid. It is in autumn, when the grain has been gathered and as winter approaches that rats and mice leave the fields and make for human habitations. One means by which they obtain entrance—as a matter of common observation—is by drain and sewage passages, especially if those be defective. (Rats themselves are apt to cause leakages and defects in improperly constructed sewers.) Granted the existence of people with actual typhoid, or of human typhoid bacillus-carriers whose excreta is among the sewage where the rats live, and which it is possible they devour, it is easy to see how millions of bacilli may be present on the body, feet, jaws and tails of these rodents, whereby food and drink may become directly as well as indirectly contaminated. In addition, typhoid bacilli may exist in the intestine of mice and rats, and their excreta in turn be a source of infection. An association with rats is traced by Mills in an asylum where the occurrence of typhoid could not be explained in any other way.

6. **Antihemolytic Action of Arsenic.**—Experiments made by Gunn and Feltham with sodium arsenite and sodium arsenate lead *them to conclude that arsenic*, whether in the form of sodium arsenite or sodium arsenate, exerts on the red blood-corpuscles an action antagonistic to that of certain hemolytic agents. The experiments, therefore, afford additional proof *in favor of the view that a protective action on the formed* red blood-corpuscles against normal or abnormal hemolytic processes may, in part at least, account for the as yet imperfectly explained benefit which results from the medicinal administration of arsenic in blood-diseases.

11 *"Nodular" Fibromyositis, an Everyday Affection. W. H. M. Telling.
12 *Influence of Chloroform When Repeatedly Administered in Small Doses. G. H. Clark.

9. **Congenital Pulmonary Stenosis.**—The authors reaffirm their previous conclusion that the secondary polycythemia in cases of congenital heart disease is seldom, if ever, rivaled in degree by the secondary polycythemia which sometimes, as is well known, occurs in chronic acquired valvular affections (of the mitral valve) and in adherent pericardium. It is more nearly rivaled by the marked secondary polycythemia occasionally associated with late stages of pulmonary emphysema, chronic bronchitis, asthma, old bilateral pleuritic adhesion, chronic interstitial pneumonia, and pulmonary fibrosis. The polycythemia in all such cases differs from the polycythemia (possibly of primary myelogenous origin) associated with chronic splenomegaly, which has been termed "erythremia," by the not infrequent absence of real cyanosis in erythremia, especially in its early stages. Just as hypertrophy of the walls of the heart is useful in so far as it compensates for mechanical defects in the valvular apparatus, so *also is polycythemia useful in so far as it compensates for* difficulties in the proper oxygenation of the blood and tissues of the body; but just as in cardiac valvular disease great hypertrophy of the heart indicates some grave defect in the valvular mechanism, so also an extreme increase in the number of erythrocytes in the blood points to great impairment of the normal process of oxygenation of the body.

11. **"Nodular" Fibromyositis.**—It is maintained by Telling that chronic muscular rheumatism, or, to quote some of its synonyms, rheumatism, muscular and tendinous rheumatism, myalgia, muscular fibrositis, etc., is a pathologic condition, the essential morbid process of which is an *inflammatory* exudation into the fibrous tissues in almost any situation in which fibrous tissue is found. This exudate leads to swelling and thickening of very variable character and degree; it may be *slight and impalpable; severe and definitely tumor-forming;* acute and transient; chronic, and eventuating in hard fibrous lumps which resist all efforts at dispersal by the ordinary means at our disposal; but under all circumstances it tends to be painful. The one almost constant symptom which results from this fibrositis is pain. These infiltrations are painful when they are pressed on, and if vigorously rubbed they swell up and the pain is greatly increased. This local pain on pressure is practically the diagnostic feature of these cases. If a patient presents himself with any of the ordinary manifestations of chronic rheumatism, as a lumbago, sciatica, pleurodynia, or a cephalagia, and with any obscure myalgic or neuralgic pain in any part of the body, Telling urges that a careful investigation should be made of the fibromuscular tissues of the affected areas. In the more recent diffuse cases there is general tenderness of these tissues, and one may not be able to feel anything which one could definitely assert to be a palpable thickening. But more usually, either with or without such general tenderness, one will find areas which are definitely, often exquisitely, tender to touch. *All that* is needed is a careful digital exploration of the structures involved. General treatment meted out to a feverish attack, with the employment of the ordinary pain-relieving drugs, *is generally sufficient to effect a cure. If the pain is at all* localized a single thorough application of massage may result in cure in this early stage. The removal of any discoverable cause, such as gastrointestinal irregularities, must be undertaken, and will not only help toward a cure, but will tend to prevent recurrences. During the more acute exacerbations drugs such as sodium salicylate, and the various means described in the acute attack produce a certain measure of relief, but recurrence is liable to occur indefinitely. To obtain a permanent cure and a complete relief from the recurrent attacks it is absolutely necessary that local treatment should be adopted with a view to obtain a complete dispersal of the indurations. Counter-irritation by blistering or cautery produces relief. Nothing, perhaps, is so efficient as the rubbing in of oil of gaultheria. Mechanical treatment must be adopted to secure a permanent dispersal. The most important of the forms are massage and systematic exercises. Acupuncture is undoubtedly of great use in relieving pain, but in Telling's experience does not produce complete dispersal of the infiltrations. In cases of fibrous nodules which will not yield to simpler measures, and which by implicating or pressing on nerves cause persistent pain, excision is not only advisable but necessary, the only caution being that the nodule must be definitely localized beforehand.

12. **Influence of Chloroform in Small Doses.**—Clark found that chloroform repeatedly administered by the respiratory passages, subcutaneously, and by the stomach in small doses rapidly kills rabbits. The liver shows degeneration of the

cells sometimes so marked that the whole center of the lobule is broken down into débris. The cells in the center of the lobule are early affected, those further out later. Fat is always present, generally in large quantities. The kidney suffers to some extent, but relatively more when the chloroform is inhaled than when injected or given by the stomach. Fat is occasionally found in degenerated cells. The spleen shows intense congestion, the sinuses being packed with red blood-corpuscles. Along with the red corpuscles an orange-colored pigment is generally present which reacts to the stain for iron. A large number of very large phagocytes are present in most cases. The average weight of the spleen was 0.46 gram heavier than the controls when chloroform was inhaled, and 0.59 gram and 0.17 gram heavier when injected and when given by stomach respectively. Degenerative changes were observed in the cardiac muscle. Fat was not observed in any of the hearts examined.

25. Hemorrhagic Colitis.—Mathieu summarizes the treatment for hemorrhage in the course of simple dysenteriform colitis as merely rest in bed, dieting, moist heat to the abdomen, lavage of the intestines and a mild purge after two or three days. The lavage should be done with an isotonic fluid at a temperature of 38 or 40 C., not injecting more than a liter at most and never with a pressure over from 20 to 40 centimeters. Done in this way, the bowel is cleansed and soothed, with no fear of exaggerating the tendency to spasm. In the severer cases he gives two injections a day of a 0.02 per cent. solution of silver nitrate, seldom exceeding a total of four or five such injections. In the chronic forms, local applications or operative measures may become necessary. The record of the latter as he reviews it is not very encouraging and the later history is not known of many of the patients cited as cured.

26. Syncopes in Chronic Colitis.—Millon and Marre have encountered cases of transient loss of consciousness in the course of an exacerbation of the intestinal trouble inducing symptoms of severe indigestion. In other cases the syncope, followed by a small diarrheic passage, is the only sign of trouble. The syncopes are brief and leave no traces, but the dread of them may become an obsession in time, and they might prove dangerous in persons inclined to arteriosclerosis or nephritis. Treatment should seek to soothe the nervous system as it is peculiarly irritable in these patients, besides treatment of the intestine. Four cases in adults are reported in detail. The oldest was a man of 67.

Annales des Maladies des Org. Génito-urinaires, Paris

December 1, XXVIII, No. 23, pp. 2115-2208

29 *Reflex Nervous Phenomena in Urinary Apparatus in Appendicitis. F. de Meo.

December 15, No. 24, pp. 2209-2304

30 *Myomatous Tumors in the Bladder. (Tumeurs musculaires lisses de la vessie.) J. Heitz-Boyer and Doré. Commenced in No. 22.
31 *Treatment of Kidney Disease by Nephrectomy. Pausson.

29. Symptoms in Urinary Apparatus from Appendicitis.—De Meo relates the particulars of six cases in Italian literature and two from his own experience in which reflex nervous phenomena, kidney colic, pain during micturition, bladder tenesmus, cystalgia, smarting in the urethra or priapism were the first signs of trouble which later proved to be appendicitis. The inflammation in the appendix evidently acted on the vesical, renal, hypogastric or pubic plexus, inducing functional disturbance. In his cases the urinary symptoms were explained by discovery of an abscess between bladder and rectum, evidently of appendicitic origin, although there was no history of appendicitis. Both patients were young men. In two of the cases from the literature these attacks of pain in the right inguinal region had been ascribed to rheumatism, the fourth simulated kidney colic with strangury. As no improvement followed a month of medical measures, the appendix was removed and all symptoms ceased. Acute retention of urine was also the predominant symptom in another case in which the lesion proved to be an encysted abscess in the pouch of Douglas, the appendicitis having run a latent course.

30. Myomatous Tumors in the Bladder.—Of the twenty-three patients given operative treatment, two died within a few days of peritonitis and one from unknown cause. The literature on the subject is reviewed in detail.

31. Indications for Nephrectomy.—Pausson concludes his review of the results of the functional tests as applied to determine the condition of the other kidney with the statement that none of them gives positive information. The confidence in the functional capacity of the remaining kidney cannot be more than presumptive at present. So many factors are involved that it is impossible to estimate them all with certainty.

33 *Mucomembranous Colitis. A. Arraga.
34 After-Treatment of Congenital Dislocation of the Hip Joint Reduced by the Bloodless Method. (Luxations congénitales de la hanche.) P. V. Badin.
35 Case of Deforming Fibrous Osteitis with Osteomalacia. S. de Souza.

33. Mucomembranous Colitis.—Arraga says that this affection is extremely common in Argentina among children, and that his experience has demonstrated that it is a manifestation of an inherited arthritic tendency. This primary arthritic tendency he ascribes to overfeeding, especially with meat and eggs. Children born with this tendency manifest it early by green diarrhea alternating with constipation. The tendency to constipation and colitis may remain through life—the result of a functional insufficiency of the digestive organs, liver and ductless glands. Overfeeding with meat and eggs aggravates this congenital tendency. Women nursing such children should subsist largely on a milk-vegetable diet, he affirms, and weaning should be postponed as late as possible.

39 Classification of School Children Who Cannot or Will Not Study. (Essai de classification des enfants paresseux.) E. Weigert.

36. Artificially Induced Pneumothorax in Tuberculosis.—Courmont reports benefit from immobilization of the lung in three patients out of his series of four thus treated. In the one unsuccessful case the tuberculous lesions were not restricted to the lungs and larynx. The method is necessarily limited to cases in which only one lung is involved and the adhesions are not too pronounced. Even ulcerative processes in the larynx may heal when expectoration from the diseased lung stops—this point is instructively brought out in his case-reports. Lesions in the intestines do not seem to be influenced by the suppression of the sputum. In three other cases, the method was found inapplicable. The nitrogen was injected in amounts ranging from 500 to 1,300 c.c., a total of 9,800 c.c. being injected in the first case between April 13 and September 1, in eleven injections. The total was 12,950 c.c. in seventeen injections in the course of seven months in the second case. The third patient was so much improved by five injections in about six weeks that he considered himself cured and declined further treatment.

Semaine Médicale, Paris

January 18, XXXI, No. 3, pp. 25-37

47 *The Tourniquet Sign of Disease with Hemorrhagic Manifestations. (Le signe du lacet.) C. Frugoni and F. Giugni.

47. **The Tourniquet Sign of Hemorrhagic Disease.**—For more than four years Frugoni and Giugni have been studying the local phenomena which develop in an affection with a tendency to hemorrhagic manifestations when a slightly constricting band is applied to the limb above. The band is not drawn tight enough to induce actual arterial hyperemia, but merely enough to cause the veins to be a little more prominent, and any tendency to a hemorrhagic diathesis is then rendered locally evident. They relate their experiences with this test applied to patients with various hemorrhagic affections, comparing the findings with those of tests of the various properties of the blood. The trouble does not seem to be with the blood itself so much as in the walls of the vessels. In some of their patients a slight traumatism at one point was followed by hemorrhagic manifestations all over the body except the face, and no means could be devised to induce them in the face; evidently the vessel walls here are exceptionally stout.

49. **Tuberculin Treatment of Infants and Young Children.**—Rohmer reports the details of six cases in which Schlossmann's method of tuberculin treatment with comparatively large doses (0.0002 gm.) was applied. The outcome was unfavorable in every instance, although at first marked benefit seemed to be derived; the underlying tuberculosis however continued its course practically unmodified. The large doses of tuberculin seemed to exert an injurious influence on the organism as a whole, bone lesions developing in some of the children while in one the tuberculosis flared up in a fulminating form after an intercurrent attack of measles.

52. **Idiosyncrasy to Cows' Milk in Infants.**—Halberstadt reports six cases and is inclined to regard idiosyncrasy to cows' milk as a symptom of a congenital constitutional anomaly. It does not manifest itself during the first days of life but develops gradually, like pylorospasm, and seems to be somewhat in the nature of anaphylaxis. The different elements of the milk seem to be at fault in different cases but the constitutional unfitness is the primal cause.

60. **Operative Treatment of Diffuse Peritonitis.**—Schmid reviews the experiences in this line in Körte's surgical service at Berlin. Rigidity of the abdominal walls and local pain indicate the danger and demand immediate operation. To wait until further signs of peritonitis develop, after perforation of the stomach or other organ or appendicitis, is to court disaster. Perforation of lower parts of the intestines has a graver prognosis. The outcome in all cases depends more on the stage of the peritonitis than on technic. Peritonitis pus is peculiarly dangerous for loose cellular tissue, fat tissue and for the fascia of the abdominal wall. The abdomen can master small amounts of infectious material but succumbs when confronted with too much. Prevention and early operation are the watchwords of success, he declares. In 358 operative cases the mortality among the 235 patients in whom the abdomen was rinsed out—which includes all the severer cases—was 40 per cent., while it was 42 per cent. in the others. The mortality was 25 per cent. for both groups in the cases in which the operation was done within three days after the onset of trouble. It was 55.4 per cent. in the "rinsed" patients operated on by the fourth day or later, while it was 69.2 per cent. in the corresponding group of the "non-rinsed" patients. This difference speaks volumes, he declares, in favor of rinsing out the abdominal cavity as the second group contained all the milder cases.

64. **Atypical Tuberculous Processes in the Lung.**—Hansemann believes that important information as to the curability of pulmonary tuberculosis can be derived from the study of necropsy findings in deaths from various causes. Diseases which do not show a tendency to spontaneous cure are not amenable to therapeutics. Therapeutics, therefore, he says, is engaged merely in cooperating with and fostering the natural tendency to heal. Unless the anatomic findings show a tendency to a spontaneous cure under favorable conditions, little can be hoped from treatment; he has never known of a case of acute miliary tuberculosis which terminated in recovery. The same can be said of acute disseminated cheesy bronchitis. Anatomic findings suggesting even a beginning of a healing process with these affections have never yet been encountered, to his knowledge. With tuberculous apical processes no recovery is known when the lesion extended below the second or third rib; the most that can be expected from treatment in these cases is to prolong life. It is impossible to destroy all the tubercle bacilli in such advanced cases. In regard to the importance of mobilizing the superior aperture—the Freund operation—he admits the usefulness of curing the rigidity of the part but thinks that this can be accomplished by gymnastics—exercises of the muscles attached to the upper rib. He emphasizes in particular the importance of this mobilization as a prophylactic measure in families with a history of tuberculosis and an inherited tendency to stenosis of the superior aperture. He is convinced that if orthopedic measures of this kind could be commenced about the age of 12 and continued to 21, the development of typical pulmonary tuberculosis might be avoided in many cases. It is the task of the family physician to warn the parents of the necessity for such treatment for their children, especially when they are growing fast and the chest is flat and narrow. In conclusion he insists anew on the necessity for antisyphilitic measures when a tuberculous process develops in a syphilitic. Typical pulmonary tuberculosis always begins in the apex, he states, but atypical forms are encountered almost invariably in children and in the aged.

67. **Salvarsan in Inherited Syphilis.**—Peiser refers to four cases in recent literature in which salvarsan taken by the nursing mother had a beneficial effect on the infant with severe manifestations of syphilis. He then describes two cases and refers to four recently reported in which no benefit was apparent although the mothers were given salvarsan systematically.

69. **Urine Reaction in Breast-Fed Infants.**—Engel and Turnau state that a black precipitate forms in the urine of breast-fed infants when 15 or 20 drops of a 2 per cent. solution of silver nitrate are added to 5 c.c. of the urine. The discoloration reaches its height in ten minutes or still earlier if the fluid is heated. There is no black discoloration with urine from bottle-fed infants.

75. **Urinary Concrements.**—Roth gives an illustrated description of a number of cases of remarkable kidney and bladder concrements and comments on the difficulty of differentiation when, as often happens, the symptoms are slight and misleading, or there may be no subjective symptoms. The main point is to bear the possibility of eventual stone formation in mind. In one of his cases nothing suggested kidney stone until the cystoscope revealed the source of the bleeding as in the kidney. Patients with hematuria are too apt to be lost sight of after the hemorrhage is over, and yet hematuria, he insists, is almost invariably the manifestation of some important urogenital affection. Mistakes will be avoided far more frequently if the cystoscope is used even with apparently merely nervous symptoms on the part of the bladder. No one should be classed as a "sexual neurasthenic" until after exclusion of all other possible causes.

82. **Poisonous Butterine.**—Dunbar's communication, giving the results of his research, was summarized in the Berlin Letter, February 11, page 435. He warns of the danger of new poisonous ingredients being used in the production of articles intended for food as the manufacturers go farther afield in search of less expensive ingredients for their products. (As stated in the Berlin Letter, January 7, page 54, the firm manufacturing the poisonous butterine advertised a reward for "discovery of the person who had adulterated the product," suggesting that it was a criminal act of revenge. But Dunbar traced the disturbances to a new ingredient used in making the butterine.)

83. **Fever With Malignant Tumors in Kidneys or Suprarenals.**—Israel has encountered eighteen cases in which a tumor in a kidney or suprarenal was accompanied by intermittent or relapsing fever. In some of the cases the fever was for a long time the only sign that anything was wrong. In twelve of the cases the cancer was confirmed by an operation and he gives the temperature curve of some in this group, showing the complete disappearance of all tendency to fever after removal of the cancer, and its persistence without much modification after merely palliative or partial operations. With metastasis the fever flares up again as also if some hitherto latent cancer germs rouse to malignant energetic growth. The outcome was less favorable in the febrile than in the non-febrile cases. The importance of suspecting cancer with fever of unknown cause is illustrated by the case of a patient at the Trousseau hospital at Paris, with a large tumor in the left kidney and intermittent fever, who was long treated on the assumption of malaria and enlarged spleen. One of Israel's patients with hectic fever but no signs of pulmonary or bronchial tuberculosis was sent to a sanatorium for lung diseases until development of signs pointing to a tumor in the kidney. Israel comments on the scanty literature on fever with renal cancer and hypernephroma, some of the most experienced clinicians not even mentioning the subject; but he declares that this must be due to inadequate study of the cases or misinterpretation of the findings or to too brief period of observation before the operation. In some patients the fever always accompanied or just preceded hematuria. The fever was observed with cancers of different histologic structure. The rapid growth of the tumor, propagation to the adipose capsule, veins or adjoining tissue favor the development of a febrile temperature but are not indispensable for it.

84. **The Phenolphthalein Test for Occult Gastro-Intestinal Hemorrhage.**—Boas remarks that the benzidin test for occult bleeding is so sensitive that the findings are liable to be misleading; even having eaten a little meat, days before, may lead to a positive response. On the other hand, the unmodified guaiacol test is not sensitive enough. Midway between them stands the phenolphthalein test which he commends to the general practitioner as more reliable than either while it

is extremely simple, the reagents used are durable, and the color reaction is so pronounced that it is impossible to mistake it. He tabulates the comparative findings with the three tests and describes the technic. The stool is rubbed up in water till it forms a thin fluid. Into this a little acetic acid is stirred; ether is then added, and the reagent glass is slowly moved to and fro until the contents are well mixed. The ether is then decanted into another reagent glass and 20 drops of the phenolphthalin reagent are added, the whole is shaken and then 3 or 4 drops of hydrogen dioxid are added. In the presence of blood the phenolphthalin is oxidized into phenolphthalein and as it is in an alkaline medium the fluid turns pink. With considerable blood the pink tint persists for some time, with very little blood the pink tint soon fades away. The reagent is made by dissolving 1 gm. of phenolphthalein and 25 gm. of potassium hydroxid in 100 gm. water and reducing with 10 gm. of pulverized zinc. The resulting red fluid is stirred or shaken over a small flame until it is entirely decolored, the phenolphthalein being reduced to phenolphthalin. It is then filtered when it is ready for use and keeps indefinitely. With much admixture of blood the reaction is pronounced even without addition of hydrogen dioxid. No meat should be eaten for a few days before the test.

90. **Treatment of Ischemic Contracture and Gangrene.**—Bardenheuer devotes about 155 pages to his study of the origin and treatment of these conditions illustrating the various points by examples from his own experience. The prognosis depends, he says, on the period in which the ischemic myositis or contracture is discovered and suitable treatment applied. This should include search for the central, causal, retromuscular or retrofascial hemorrhage probably responsible for the trouble or measures to prevent its development, treatment of the primary acute ischemic myositis and means to correct the resulting contracture. The conditions are graver in different regions.

95 * [illegible] Syphilis. (Serodiagnose der Syph- [illegible] von Natr. glycochol. unter Heranziehung des Cholesterins.) O. Herman and A. Perutz.

95. **Improved Serodiagnosis of Syphilis.**—Herman and Perutz having simplified the precipitation test devised by Elias, Neubauer, Porges and Salomon report positive results in 108 out of 134 cases of syphilis, while the Wassermann reaction was positive in only seventy-two out of 102. Their test consequently gave 4 per cent. more positive reactions than the Wassermann technic. In eighty-nine control cases traces of precipitation were observed in only a single instance, the findings in all the other cases being negative. They commend their modification as practically reliable, much simpler than the Wassermann test and as destined to wide application in general practice for the serodiagnosis of syphilis. The technic requires only a little blood, which is allowed to stand for a few hours. The clot is then detached with a platinum wire, the serum is centrifugated, the sediment removed, and the serum is then inactivated by heating exactly to 65 C. for half an hour in the water bath. The serum should not be powerfully hemolytic. The reagent is a mixture of 2 gm. sodium glycocholate with 0.4 gm. cholesterin and 95 per cent. alcohol to 100 c.c. This mixture is diluted with distilled water, 1 to 20. The second reagent is a freshly made 2 per cent. aqueous solution of sodium glycocholate. To 0.4 c.c. of the serum are added 0.2 c.c. of the twenty times diluted reagent 1, and 0.2 c.c. of the 2 per cent. sodium glycocholate solution, and the whole is well shaken. The test tube is then plugged with cotton and allowed to stand quietly at room temperature for twenty-four hours. After twenty-four hours distinct precipitation indicates a positive reaction, but if the fluid is merely turbid with fine flakes and no precipitate thrown down the reaction is regarded as negative. The findings in 223 cases are tabulated for comparison, the nonsyphilitic cases showing, with a single exception, a constantly negative reaction.

97. **Inflammation of Adipose Capsule of Kidney.**—Bussenius and Rammstedt remark that the syndrome resulting from mere congestion and infiltration of the adipose capsule has not been much studied. Soldiers are especially liable to it as result of contusions, kicks, riding unruly horses, lifting heavy weights, etc. Sometimes the syndrome comes on insidiously but more often it comes on abruptly with chill and high fever. The temperature rises in a series of peaks, then remains continuous for a day or so, then becoming remittent with low morning and high evening curves. Even a difference of 2 C. (3.6 F.) between morning and evening temperatures is not conclusive of suppuration. The pulse-rate is generally faster than the temperature would warrant, and sweats may also be observed. The digestive apparatus usually shares in the disturbance, and constipation follows after a period of diarrhea in some cases. Sudden pain is characteristic, not always in the kidney itself, but below, and pressure increases the pain. It may radiate to the stomach, bladder, cecum, perineum or genitals. The chief tender point is found just below the twelfth rib and pressure here generally brings on the pain anew, as also deep breathing, coughing and moving the trunk. There is some swelling of the lumbar region unless the trouble is in the front of the capsule. Seven cases are reported in detail. They show that the patients can recover under medical measures alone in some cases. The general condition is the criterion; if the patient does not seem to be growing worse, expectant treatment is justified. Repeated exploratory punctures are useful, and the hot-air apparatus frequently renders good service. In the authors' cases, potassium iodid seemed to have a decided influence in promoting absorption of the products of the inflammation. Under these measures three of the patients recovered entirely, although slowly, but in the other cases the process passed into a suppurative stage, and recovery followed evacuation of the pus. They advise operative treatment, even if no pus is evident, if the general condition seems to be growing worse and the patient weaker. The pus may make its way into the intestines, bladder or ureter and a spontaneous cure may thus be realized.

98. **Tuberculous Articular Rheumatism.**—Melchior remarks that only four cases have been published to date in which the tuberculous nature of the articular rheumatism has been established beyond question, and to this list he now adds a fifth. The patient was a girl of 19 with glandular tuberculosis as a child and later a tuberculous process in the lower jaw compelling total resection in 1909. Twelve days after the operation, moderate fever developed with multiple acute swelling of joints, the syndrome deceptively resembling that of acute articular rheumatism except for the relatively low fever, the slight painfulness of the lesions in the joints, their torpid character and the absence of the sweats characteristic of ordinary acute articular rheumatism. Tubercle bacilli were found in the blood. The joint lesions seemed to subside

spontaneously so that by the end of three months nothing was left of them except a slight thickening of one knee. The patient died in a few months from amyloidosis, independent of the joint processes. Necropsy revealed tuberculous nodules in the synovial membranes of the joints which had been involved. During life inoculation of animals had been negative, showing that the presence of tubercle bacilli in the synovial membrane does not necessarily imply their presence in the effusion in the joint.

99. **Syphilitic Spondylitis.**—Ziesché reports a case and reviews recent literature on this subject, tabulating the details of eighty-six cases he has found on record. The affection is generally considered as unusually malignant but this, he thinks, is because it is not recognized until it is in an advanced stage. In the case of a child the condition received treatment early and improvement was soon realized. In this case there was not the slightest reason for suspecting syphilis; the first sign of trouble was a gibbus in the region of the first and second lumbar vertebræ. The tuberculin tests were negative but the Wassermann reaction was positive although no swollen glands could be discovered. Investigation disclosed syphilis in the child's nurse. Mercury and iodid brought rapid improvement. Ziesché is convinced that syphilitic spondylitis is more frequent than generally suspected; in the mild cases the lesions heal and nothing is known of them. In this compilation the age was mentioned in fifty-three cases, and 28 per cent. of the patients were between 20 and 40; 22.7 per cent. under 10, and 11.3 per cent. between 50 and 60. The cervical vertebræ alone were involved in sixty-one of the eighty-eight cases; the thoracic in twelve; both in one, and the lesions were diffuse in four cases. In over 41 per cent. only one vertebra was affected, two vertebræ in over 28 per cent., and four in 5 per cent. In eight of the sixty cases of syphilis of the cervical vertebræ death occurred suddenly. Thirty-eight of the patients recovered under appropriate measures although left with more or less functional disturbance. Mercury and potassium iodid should be given in large doses. he says, even transient salivation should not be allowed to interrupt the treatment, and the iodid should be continued for a time after apparent recovery.

102. **Acute Dilatation of the Stomach After General Anesthesia.**—Payer states that a fatal termination occurred in over 53 per cent. of the cases of this trouble in the literature and his own experience. The diagnosis in time is more important here than in almost any other affection, he emphasizes, as change of position is the only and the efficient cure. The trouble has been called by twenty-one various names, including pseudo-ileus, mesenteric incarceration of the bowel and also acute paralysis of the stomach. The initial shock, the increased peristalsis and antiperistalsis and secondary acute dilatation of the stomach form the general description of the syndrome, but Payer is convinced that the trouble is in reality a primary paralysis of the stomach from the toxic action of the anesthetic. For several years he has been examining the stomach functioning before and after operations under general anesthesia, and he found more or less of a tendency to paralysis of the stomach in nearly every instance. This paresis is accompanied by gastrorrhea and each in turn aggravates the other; if the patient lies on his back serious trouble may follow while if he is turned on his right side the stomach contents flow spontaneously out of the stomach. Atony of the stomach is almost invariably evident as the patient rouses from the anesthetic; sometimes the lower margin of the stomach will be found below the umbilicus, but this atony generally subsides so that no trace is left after from twelve to twenty-four hours. Postoperative vomiting is directly connected with this atony; in every case in which it persisted longer than this, the atony also persisted. The critical period is from the third to the fifth day, when a more liberal diet is allowed. Even although there may be no symptoms, investigation will show how the lower margin of the stomach drops lower, the effect being more pronounced the shorter the interval since the anesthesia. Errors in diet have a marked influence on the development of the paresis, and children are especially liable to it. Even a week after the anesthesia, acute dilatation of the stomach and distention may occur. Drainage of the peritoneal cavity is also liable to affect the stomach and induce atony, as he observed in two striking cases—an appendicular abscess in a child and a liver abscess in a man. Payer now makes a point of having the patient lie on the right side if there is any tendency to vomiting after from twelve to twenty-four hours. This generally answers the purpose but if disturbances persist he gives a chamomile tea enema, with the patient still lying on the side, repeating the enema frequently at need, giving nothing by the mouth. In very severe cases the knee-chest position was the only means of final relief; this never failed. He never had to resort to lavage of the stomach. During the last two years he has been giving oxygen freely in connection with the anesthesia, to paralyze the toxic action of the chloroform, and imagines that he has noted a favorable influence on the gastric paresis. This postnarcotic gastric paralysis, as he calls it, has been observed after the most diverse operations. He lists also the predisposing factors as they have been recorded in the literature and also the factors that proved the last straw. The latter list includes overfilling of the stomach with food or fluids, the toxic action of veronal, or of scopolamin, dread of the operation, abdominal straining, compression of the abdomen by a plaster cast, tamponing the abdominal cavity (Nakahara), compression of the duodenum by tampons, wandering kidney or liver. drastic purgative (Jacoby), and saline purges, increasing the stomach content by osmosis (Selby).

109 Leukemia with Skull Tumor in a Year-Old Child. O. Herbst.

104. **Formula for Estimating General Condition of Infants.**—Bauer thinks that a good estimate for comparison can be obtained by dividing the weight in grams by six times the length in millimeters, plus three times the age in days. The formula for this is: $W \div 6(L+3D) = X$. Weight ÷6(Length +3(Age in) days)=the unit of health.

108. **After-History of Children with Eczema.**—Moro and Koll have traced the fate of sixty-three boys and thirty-seven girls between 3 and 11, known to have suffered from chronic eczema during infancy. The majority were found apparently healthy. No special tendency to the rheumatic or gouty diathesis could be discovered in these children or their parents and no evidence of special overfeeding. Another point brought out is the frequency of spasmophilic phenomena in infants with the exudative diathesis. The coincidence is too striking to be merely casual; it seemed rather as if both were clinical manifestations of one and the same diathesis. The total findings are tabulated under various headings and compared with similar data from control groups.

119 [illegible] of Natural Radio-Active Mineral Water. F. Hirz.

111. **Gastrospasm.**—Waldvogel is convinced that true gastrospasm is a very frequent if not the most frequent affection of the stomach, far more common than the often mistakenly

diagnosed gastric ulcer, while the symptoms resulting from the gastrospasm are more constant than those from altered secretion. The prognosis of gastrospasm is favorable under appropriate treatment, that is, sedative measures to reduce the irritability of the innervation of the stomach and of the nervous system in general. He differentiates the condition by the level of the lower margin of the stomach after the patient has taken an effervescing mixture: 4 gm. of sodium carbonate and 4 gm. of tartaric acid, each in 100 c.c. of water. He gives the mixture two or three hours after breakfast or four or five hours after dinner and has the patient recline. Finger percussion from the nipple downward shows that the inflated stomach under these conditions, in a healthy and not excited person, always reaches to the umbilicus. The findings are much more reliable with this test, he thinks, than with bismuth and radiography. He accepts gastrospasm when with the complaints of oppression, pain and eructation of pure air without odor or taste, the lower margin of the stomach is found to be a handbreadth above the umbilicus and only two or three fingerbreadths below the costal arch. The contraction of the stomach is most marked in the region nearest to the umbilicus. In some cases, the entire effervescing mass was explosively vomited—a further confirmation of the assumed gastrospasm in the absence of palpable stomach lesions. The gastrospasm is generally observed with clinical pictures in which spasms of all kinds are common. Lead poisoning is a frequent cause, and also abuse of tobacco, arteriosclerosis of the abdominal vessels and uremia. But chief of all causes is general neurasthenia, and various signs of nervous excitability and abnormally low nervous threshold generally accompany the gastrospasm, such as tremor of the fingers and tongue, accelerated pulse, insomnia, etc. Gastrospasm on the other hand is seldom encountered with hysteria. He adds that in one case the patient dropped tobacco completely after long abuse and a condition of atony of the stomach followed which lasted for several weeks.

113. Premonitory Signs of Thrombosis.—Michaelis had a fatal case of pulmonary embolism in the first week he set up practice for himself; this was followed by two non-fatal cases of embolism in less than six months and five others in two years. Since then he has not had thrombosis develop in any case and he is convinced that his careful prophylactic measures now are responsible in large part for the absence of this serious puerperal and postoperative complication. It always gives warning, he declares, in the form of a very slight rise in temperature, possibly transient and unnoticed unless the temperature is taken four times a day and the thermometer left in place for fifteen minutes at least. This alone permits the recognition of a temperature above 37.5 C. (99.5 F) at any time during the day. He does not say, of course, that every subfebrile temperature is an index of the onset of thrombosis, but that anything over 37.5 C. suggests the necessity for caution and close supervision of the patients, guarding them against any violent movement, any excitement or fright, and keeping the bowels loose with oil injections, and a mild laxative and suitable diet. If the patient is allowed to get up early, heedless of the warning of the slight subfebrile temperature, danger looms large. He is convinced that these measures and keeping the patient in bed for a week as quiet as possible, have contributed in no small proportion to the smooth recovery of many of his patients showing slight transient subfebrile temperature, thus tiding them past the danger stage.

117. Direct Massage of the Heart in Apparently Fatal Chloroform Accidents.—Jurasz reports another case in which the patient's heart and lungs ceased functioning suddenly during a long operation; by prompt massage of the heart, with the hand introduced in the laparotomy wound and squeezing the heart through the diaphragm, the vital functions were restored. The patient was a woman of 50 whose pylorus was being resected for cancer. All went well for an hour, but as the duodenal stump was being attended to, the apparently fatal accident occurred. Artificial respiration was kept up at the same time as direct massage was applied to the heart and oxygen pumped into the lungs. The heart showed the effect of the massage in two minutes and the patient began to breathe spontaneously. The massage and artificial respiration were then suspended, but immediately the syncope came on again. The artificial respiration and heart massage were then resumed and in a minute the vital functions began again. The operation was then concluded under a few whiffs of ether, with no further disturbance. The pulse at the close was small but regular and recuperated under a few injections of camphor so that no further stimulants were necessary. Eight minutes in all elapsed between the first stoppage of the heart and its definite revival and no further disturbance in its functioning occurred although the operation was continued and more of the anesthetic given. Jurasz has found records of sixty-four cases of direct massage of the heart in the literature. The patients were resuscitated in two out of the twenty cases in which the massage was done through the chest wall and in eleven of the twenty-six cases in which the heart was massaged through the diaphragm. None of the patients survived when the hand was introduced through an opening made for it in the diaphragm. The total recoveries thus number thirteen or 23.3 per cent. of the cases, but temporary success was obtained in fifteen additional cases. He advises incising the epigastrium in five minutes at latest after arrest of the heart functioning and seizing the heart between the thumb and two fingers, to squeeze it rhythmically about sixty times a minute, supplementing this with artificial respiration and insufflation of oxygen if possible. The massage and artificial respiration should be kept up for a time after the first spontaneous movements. It is sufficient to sterilize the field with tincture of iodin, massaging with the gloved hand.

120. Action of Digitalis in Arrhythmia.—Edens states that the newer methods of examining the pulse and heart action have only strengthened our confidence in digitalis. When the drug fails to act—which used to be ascribed to impurities in the drug—we now know that it is because the heart affection is of a kind which is not influenced by digitalis. This very failure is proving a most important aid for diagnosis and prognosis, as he illustrates by a number of case-reports and tracings. The chief element in the action of digitalis, possibly, is the promotion of the circulation through the coronaries by the lengthening of the diastole and the better filling of the arterial system. When mechanical obstacles, such as aortic insufficiency, interfere or when the acceleration of the pulse is the result of nervous influences rather than of insufficiency of the heart muscle, then digitalis is liable to fail. The drug is thus liable to render good service, he asserts, in differentiating the various kinds of extrasystoles and in improving the contracting power of the heart. It may seem to induce a bigeminus rhythm of the entire heart but under its continued administration the rhythm alters so that the contraction of the auricle occurs simultaneously with that of the ventricle systole while the interval between the first and second systole persists unmodified. These are the cases described by Hering as "pseudo-alternans," and Edens has encountered five such cases; the digitalis induced bigeminus of the ventricles while retarding the auricle beat.

123. Action of Diuretics.—Meyer reports experiences which show that the improvement in the circulation liable under digitalis may be followed by very much increased elimination not only of urine but of sodium chlorid in the urine. In a case of extreme dropsy with only 360 c.c. of urine, under digitalis the urine increased in two days from 360 to 3,300 c.c. and the sodium chlorid from 2.9 to 26.4 gm. A similar remarkable diuretic action was observed in a case of tuberculous polyserositis under calomel and digitalis, the figures being almost identical with those in the first case. He explains this action of calomel as due to the absorption of the fluid effused into the intestines under the influence of the calomel.

135 Politzer's Air Douche During Deep Inspiration. (Neuere Modifikation meines Verfahrens zur Wegsammachung der Eustachschen Ohrtrompete.) A. Politzer.

130. **Treatment of Bronchitis by Dry, Hot Air.**—Schmidt has been systematically applying this measure for a number of years and has found it useful in simple chronic catarrhal inflammation of the larynx and bronchi; it is less effective in emphysema bronchitis and bronchiectasia, and is unreliable in tuberculous pulmonary and laryngeal processes. The patients inhale the superheated air through a tube with removable glass mouthpiece; the air is filtered through cotton, dried by passing through calcium chlorid and heated in a small chamber inside a large, asbestos-coated stove heated by gas or electricity. A thermometer is mounted in the tube near the mouth. The patients experience great relief from the dry hot air thus inhaled through the mouth and expelled through the nose and in many cases the bronchitis seemed to be permanently cured.

131. **Infant Feeding.**—Pfaundler suggests, as a readily remembered formula for a healthy infant, taking cow's milk to one-tenth of its weight in grams, adding carbohydrates to one-hundredth of its weight, and water to bring the whole to 1 liter; the whole is divided into five portions and as much of each portion given as the child drinks with relish. This formula is useful from the second to the sixth month; and may be modified according to the child's individual digestive functioning. He prefers for the carbohydrate up to the fourth month sugar and oatmeal gruel, after the fourth month a 2 to 4 per cent. wheat, flour or barley gruel.

132. **Resection of the Posterior Nerve Roots for Spastic Paralysis.**—Foerster states that this operation has now been done in forty-five cases to date, including twenty-seven of Little's disease. The best results have been obtained in Little's disease, a large number of totally bedridden patients having been restored to their feet. Satisfactory results have also been obtained in a case of tuberculous spondylitis, in one of a traumatic transverse lesion of the spinal cord, and in spastic paralysis of the legs following hydrocephalus or encephalitis in childhood. The results were disappointing in the five cases of multiple sclerosis. In five cases of spastic paralysis of the arm after hemiplegia good results were obtained in three but only moderate benefit in a fourth. A fifth patient whose operation dates from eight weeks is already beginning to use his arm which had been totally paralyzed before the resection of the posterior roots. The majority of the patients have thus been benefited by the operation. The principles and technic were described in The Journal, Oct. 16, 1909, page 1342.

133. **Operations on the Stomach.**—Küttner comments on the exceptional prevalence of gastric cancer in southeastern Germany; in the last three years the surgical clinic at Breslau in his charge has had 426 patients with certain gastric cancer and 258 suspects, with 130 with non-malignant surgical gastric affections. About 30 per cent. of the cancer patients had suffered for years from stomach trouble while the others had noticed gastric symptoms only for less than six months. In 10 per cent. of the cases there had been *no* pain; in 20 per cent. no vomiting; in 7 per cent. no loss in weight—usually the patients had lost from 20 to 30 pounds. In a very few cases there had been nothing to attract attention to the stomach, the patient complaining merely of lassitude and loss of weight. In 31 per cent. the palpation findings were negative. There was no hydrochloric acid, or merely traces, in 73 per cent.; lactic acid was noted in 57 per cent., and traces of bleeding in only 61 per cent. In a few patients both the motor and secretory functioning of the stomach seemed to be entirely normal. He performed a radical operation in 102 cases, using the Billroth II technic and Murphy button, silk sutures and plastic reenforcement of points exposed to special stress. The immediate mortality was 24 per cent. mostly from defective suturing or complications on the part of the lungs, pneumonia or cachexia. To date, after an interval of from one to three years, 37.5 per cent. of the patients are still living; the proportion of cured after three years was 30 per cent. in his previous series. Nearly half of the patients who had gastro-enterostomy done for a callous gastric ulcer have succumbed since to gastric cancer, and only 16 per cent. are still in good health of those whose condition is known.

134. **Treatment of Obstetric and Gynecologic Hemorrhage.**—Among the other measures described, Krönig expatiates on the success of compression of the abdominal aorta by a tourniquet and pad applied to the artery. This seems to answer the same purpose as the Momburg technic while it does not have the unpleasant by-effects of the latter, he says. The aorta compressor devised by Gauss has been applied in 100 cases and has proved eminently useful: its unwieldiness however, gives the Momburg technic the advantage outside of an institution. He comments on the transformation in the conception of uterine hemorrhage in the last few years, the defective functioning of the ovaries now being incriminated rather than the uterus. Treatment therefore is directed more to the ovaries and curetting of the uterus is regarded now as a mere symptomatic measure, no longer causal treatment. The aim should be to act on the ovaries directly or indirectly by way of other ductless glands, possibly by organotherapy, or radiotherapy. The Roentgen rays have shown great efficacy in this respect, and are proving, he says, a powerful means of treating climacteric hemorrhage, menorrhagia during the forties and in hemorrhage with uterine myomas. Over seventy patients have been given systematic radiotherapy for myoma and, with the exception of two cases in which the course was not completed, all the patients were clinically cured and the growth of the myoma arrested or it has entirely retrogressed. The Roentgen-ray treatment has superseded operative measures at his clinic as it has so many advantages over the latter and the disturbances from the Roentgen menopause are comparatively insignificant as it is brought on so gradually. The only objection is the expense. He remarks in conclusion that no progress seems to have been realized in late years in the management of uterine hemorrhage from cancer, gonorrhea or tuberculosis. With hemorrhages at puberty and chlorosis, radiotherapy is not possible on account of danger of injury of the ovaries; he has obtained excellent results however in such cases from sweating procedures in addition to iron, keeping the patients in bed for three or four weeks. Even when all other measures had failed this treatment proved successful.

148 *Salvarsan in Syphilis. (Bemerkungen zur Ehrlich-Debatte.) E. Finger.

143. **Obese Children.**—Neurath discusses pathologic obesity in the young; it is characterized by the local preponderance of the accumulations of fat in the subcutaneous tissue and by the association with other physical anomalies. He describes a case in which a boy of 10 weighed 36.8 kg. (about 80 pounds) while only 109 cm. (43 inches) tall. The child measured 83 cm. (33 inches) around the waist and 53 cm. (21 inches) around the head, and complained of disturbances in vision in the evening, headache and dizziness. A course of thyroid treatment had a marked influence on the obesity. The facts observed in this case compared with others like it in the literature suggest, Neurath thinks, a tendency to hydrocephalus with compression of the hypophysis from the distention of the third ventricle interfering with the functioning of the hypophysis. The obesity seemed to have developed suddenly after scarlet fever three years before, and Goldstein has reported three cases which he explains as hypophysis obesity following a serious meningitis. Babonneix has also reported six cases of obesity in children; all were remarkably short, and in all the head was unusually large. The obesity in one had followed scarlet fever. Neurath has also reported another case in which hydrocephalus in a child caused symptoms suggesting a cerebellar tumor plus obesity. The symptoms finally subsided, confirming the assumption of hydrocephalus without a primary tumor, the distention of the third ventricle downward accounting for the symptoms observed. The obesity resulting from this cause is characterized especially by accumulations of fat in the abdomen, buttocks and chest, unusually short stature, and sometimes by symptoms of pressure on the cerebellum. In two other cases the obese children had epileptiform seizures; the syndrome was of the type described by Tandler as eunuchoid obesity, the result of a functional incapacity, hypoplasia of the interstitial tissue of the ovaries or testicles, the internal secretion regulating the secondary sexual characteristics and the course of ossification. The epileptiform convulsions suggested an organic affection of the brain apart from true epilepsy. Neither of the children had reached puberty.

145. **Transient Partial Blindness.**—Pichler suffers himself from recurring scintillating scotoma and his study of the subject shows that the attacks are not only analogous to migraine but are amenable to the same treatment and prophylactic measures. There seems in most cases to be a hereditary predisposition which is enhanced by any cause weakening the nervous system or inducing vasomotor disturbances. The partial blindness itself we seem to be unable to influence but the succeeding headache can be warded off or mitigated by sedatives. If the patient feels the slightest sign of an impending attack, immediate cessation of work, lying down for half an hour, and eating a light lunch will often dispel the attack. Pichler's attacks are generally preceded by a bright spark floating before his eyes; if he is able to drop work at once and lie down for half an hour there is no further trouble, but if he keeps at work the typical attack and headache follow. He found marked neurasthenia in thirty-nine of his fifty-three patients, and about the same number stated that the attacks came on after long-continued close eye-work. In treatment the main point is to discover the actual underlying cause in each case and by hygiene and suitable measures keep the vital functions in good order.

148. Salvarsan.—Professor Finger is chief of the clinic for skin diseases and syphilis at the university of Vienna, and he insists that salvarsan should not yet be placed in the hands of the general practitioner as it has not been sufficiently studied in respect to the technic of administration, dosage and indications, especially as he and others have observed injurious by-effects from the drug. It is immaterial, he continues, for the practitioner to know how these by-effects can be explained. It is not enough to assure him that the by-effects and fatalities are not yet positively known to be the work of the new drug. What he must be assured before the drug is offered for general use is that the untoward effects sometimes observed are certainly not the work of the drug which he is being urged to use. Besides, Finger adds, even Ehrlich himself admits that one of the fatalities recorded was the direct consequence of the administration of salvarsan. [The injurious by-effects to which Finger refers were mentioned in THE JOURNAL, January 7, page 83, in an abstract of his article on the subject.] He states that similar by-effects have been observed in a number of other cases since; the clinical picture is practically the same in all. He refrains from comment on principle in order not to bias his judgment of the drug which has certain undeniable advantages, wishing to regard even the by-effects from the optimistic rather than the pessimistic standpoint. He comments further on Igersheimer's conclusions that salvarsan cannot harm a healthy eye because it seems to cure syphilitic eye lesions; this assumption does not necessarily follow. The predilection for the drug may vary in the healthy and the diseased optic nerve. Igersheimer's further statement that large quantities of arsenic were refound in the animals' eyeballs in his experimental research, even although no appreciable harm resulted certainly suggests caution. The frequency of the occurrence of by-effects with salvarsan cannot be compared with those from mercury as each new day may bring new developments while the matter is practically settled for mercury. Finger also comments on Martius' statement that extensive necrosis at the point of the subcutaneous or intramuscular injection was observed in every one of the twelve cadavers he had opportunity to examine two or three weeks after injection of salvarsan. [Martius' communication was summarized in THE JOURNAL, February 4, page 388.] Finger also calls attention to the fact that a distinction must be made between the frequency of syphilis as a cause of eye disturbances and the frequency of eye disturbances in the course of syphilis. Syphilologists know of the eye disturbances only from the complaints of the patients, while the ophthalmologists discover disturbances which escape the notice of the attending physician.

156 Ec ction. M. Semon.

154. **Tuberculosis of the Placenta.**—Novak and Ranzel report ten cases of tuberculous placenta; tubercle bacilli were found in the placenta in seven. They review the history of this subject and the conclusions that might be drawn from their and others' findings in regard to the marriage of tuberculous girls and sterilization of tuberculous married women.

155. **The Cicatrix After Cesarean Section.**—Scheffzek has had spontaneous rupture occur after Cesarean section at a previous pregnancy in two cases in his experience. In ten other cases labor in women who had had Cesarean section done in former years was abnormally prolonged; in one case labor lasted for sixty-eight hours. In five cases Cesarean section had to be done anew and in four women premature delivery was artificially induced but version and forceps were required to terminate it. His experience shows that the cicatrix of the extraperitoneal Cesarean section is far stronger than that of the classic technic. Section in the body of the uterus necessarily impairs the child-bearing faculty much more than the extraperitoneal technic. Even when there were suppuration and infiltration during the healing of the extraperitoneal section yet there was no fixation of the uterus or displacement from retraction of the cicatrix. The extraperitoneal technic has been applied in seventy-one cases to date and it is so much simpler, he thinks, than the classic technic that he regards it as applicable by the general practitioner even under primitive conditions. He has frequently operated in this way without an operating table, in a room hastily arranged for the purpose, and obtained the same favorable results as in a well-equipped clinic.

157. **Ligation of Veins in Suppurative Thrombosis of the Portal Vein.**—The Journal, Aug. 28, 1909, page 753, mentioned the successful outcome of ligation of the mesenteric veins in a case of portal thrombosis following appendicitis. Sprengel recently encountered a case of the kind and applied the same measure in treatment. His patient was a man, aged 29, with a first attack of appendicitis with perforation. Sprengel recently encountered a case of the kind and applied two days after the operation had been first proposed and found then that the ascending colon had no well-developed mesentery and that the retroparietal peritoneum was exceptionally fat. These facts may have been responsible for the failure in this case. The ligation did not fully answer its purpose and the pylephlebitis continued its fatal course, involving even the finest ramifications of the portal vein. A single case of failure is not decisive, however, but Wilms' successful case is still the only one on record.

158. **Glycerin as a "Laxative" for the Bladder.**—Franck has had scarcely a single failure since he has made a practice of injecting from 15 to 20 c.c. of a 2 per cent. boric acid-glycerin into the bladder without attempting to draw the urine. He injects it without a catheter, with force enough to send it past the sphincter at the outlet of the bladder. About 10 c.c. escapes from the urethra but enough gets into the bladder to answer the desired purpose, stimulating the "peristalsis" of the organ so that spontaneous evacuation of urine follows in twenty minutes at most. This is now his routine practice after all abdominal operations and he has found it useful also in paralysis of the bladder from mechanical and nervous causes. Even strictures and enlargement of the prostate are transiently favorably influenced by this liquid catheter, as he calls it.

160. **Epidural Injections for Sacral Pains.**—Albrecht has applied Cathelin's technic in fifty-three cases of severe pains in the sacral region without appreciable disease in the genital organs. The result was the complete cure of the pain in 72 per cent. while the benefit was brief or no benefit was observed in 28 per cent. His experience shows that the procedure is particularly useful in treatment of functional bladder disturbances, in idiopathic pruritus vulvæ and for coccygodynia. He injected from 30 to 40 c.c. of physiologic salt solution, with or without local anesthesia. In two out of three cases of enuresis a cure was obtained by a single injection, as also in nine out of sixteen cases of severe functional neuroses without pathologic findings in the abdominal organs or genitalia. Most of these patients had long been under treatment in the hospital without appreciable benefit. In a case of exophthalmic goiter with pain in the lumbar and sciatic regions, the pain subsided for three days and then returned but disappeared permanently after a second injection with no recurrence during the five months to date. In another case a complete cure was realized by this means after failure of systematic and repeated courses of other measures for relief of intense sacral pain and idiopathic pruritus in a woman with premature menopause. [The technic was described in The Journal, July 13, 1901, page 150.] Equally favorable results were obtained in eleven out of thirteen cases of severe sacral pain persisting after apparent cure of old chronic inflammation of the uterine appendages. He thinks it possible that the sacral pain in these cases was a morbid pain-habit and that this habit was broken up by the single injection. Some of these patients had been in the hospital for from six to fifteen weeks under a course of treatment to promote absorption of the products of inflammation.

168 *The Scapula-Angle Sign of Tuberculous Pulmonary Lesions. C. A. Crispolti.

168. **The Scapula-Angle Sign of Tuberculous Pulmonary Lesions.**—Crispolti states that the "acromion symptom" to which O. Kuthy has recently called attention is nothing but Baccelli's scapula-angle sign which has long been taught in Italy as an important indication of a disease process in the lungs causing the wall of the chest on that side to lag behind the other in the excursions of respiration. Baccelli found that this difference in the excursions was most marked at the superior angle of the scapula, at the inner extremity of its upper border, and that this difference was apparent even when the lesion was in an incipient stage. Kuthy devoted his attention to the movements of the acromion, and calls it the acromion symptom. He found it pronounced in 99.3 per cent. of 356 tuberculous patients examined, and in the eighty-five cases in which the trouble was bilateral, the sign was pronounced on the side most involved.

RETROPERITONEAL SHORTENING OF THE ROUND LIGAMENTS*

F. F. SIMPSON, M.D.
PITTSBURG

I take it that the following propositions are generally conceded, and are accordingly excluded from this discussion.

1. Many displacements cause no symptoms and require no treatment.
2. Many displacements cause discomforts which may be easily and completely relieved by well-fitting pessaries.
3. In many instances discomforts due to displacements could be best relieved by operation were there not complicating affections, pulmonary, cardiac, renal, thyroid, etc., which would render operation unduly hazardous. In such cases pessaries serve a useful purpose.

There remain, however, many displacements, some simple and others complicated, which require operative correction. It is to this class alone that my remarks will refer.

The last decade has done much to crystallize our views regarding the normal position of the uterus, the mechanism of posterior displacements, the rôle played by coincident affections and the relative degrees of discomfort due to each and the many ways by which displacements may be corrected, with their respective advantages and defects.

NORMAL POSITION

The normal relative positions of the uterus and vagina are rarely given in text-books of anatomy, obstetrics or gynecology. Dissections and frozen sections of the female pelvis are misleading. They are usually made after fermentation has caused distention of the alimentary canal, including the rectum. The anterior and posterior walls of the rectum are normally in contact except when gas is being expelled, or at the time of defecation. Text-book illustrations usually show the rectum enormously distended. Adapting the illustrations of four well-known text-books to the scale of a normal mature woman, we find both the rectum and the vagina inflated to a diameter of 1½ to 3 inches. This inflation of the canals occupies nearly the entire anteroposterior diameter of the pelvis. This distortion pushes the uterus and vagina forward, the illustrations making them appear almost vertical, and almost in a straight line. As they appear to be on end the uterus is raised from its normal pelvic position to become an abdominal organ.

Normally, however, the vagina is almost horizontal, runs almost directly backward, and the uterus is directed forward at an acute angle. This horizontal position exerts *an important influence in preventing* prolapse, whereas the vertical position favors telescoping.

We have three chief factors which prevent uterine prolapse or hernia: (1) the pelvic floor; (2) the uterine ligaments, and (3) the normal acute angle between the uterus and vagina (with the cervix as a fairly fixed point), which causes the intra-abdominal pressure exerted from above to close the vaginal slit firmly.

It is a wise provision of Nature that normally closes the oblique opening through the pelvic floor more and more tightly as intra-abdominal pressure increases. This is effected by rendering the vaginal canal and the uterus which run in opposite directions, more and more nearly parallel and horizontal. This method of closure is analogous to that of the ureter as it enters the bladder.

In order that the uterus may remain in its normal position it is necessary to maintain to a considerable degree the functional value (1) of the pelvic floor; (2) of the supporting ligaments which radiate from the cervix, and (3) of the round ligaments, which act as guy-ropes.

MECHANISM OF RETROVERSION AND OF PROLAPSE

With the cervical attachment of the base of the broad ligaments acting normally as a pivotal point, the fundus will remain forward if the round ligaments are normal. If the round ligaments are stretched (as by a fall or after delivery), however, the fundus may turn backward to any degree, though the integrity of the broad ligaments and of the pelvic floor remains unimpaired. As a matter of fact, however, posterior displacements are very often, if not usually, accentuated by an injury to the pelvic floor or by stretching of the supporting (i. e., radiating) ligaments, or by both.

Should both these supports be impaired at the same time (i. e., the pelvic floor and radiating ligaments), the direction of both the uterus and the vagina is rendered more nearly vertical and they assume more nearly a straight line. When such mechanical conditions exist, it is easy for the uterus to be telescoped into and through the vagina. Such a prolapse implies:

1. A shortening of the posterior wall of the vagina as by a perineal tear.
2. The stretching of the sacro-uterine ligaments permitting the cervix to move forward.
3. Elongation of the round ligaments permitting the fundus to tilt backward.
4. Stretching of the broad ligaments, permitting the uterus to sag downward.

The degree of prolapse and the speed with which it develops varies with the type of work and other causes for varying intra-abdominal pressure, such as straining at stool, etc.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixty-First Annual Session, held at St. Louis, June, 1910. This article is part of a symposium, other articles of which appeared last week and further on in this issue.

COINCIDENT AFFECTIONS

In my experience about 70 per cent. of patients requiring operation for posterior displacements of the uterus have also suffered from associated diseases of the ovaries, tubes or appendix. Fortunately, the medical profession has emerged from that period when it was customary to attribute all discomforts of doubtful origin to the genital tract. By virtue of close scrutiny and strict adherence to the laws of logic many so-called reflex uterine pains have been reduced to their correct analysis and have assumed the concrete form of gallstones, gastric and duodenal ulcer, floating kidney, ureteritis, chronic appendicitis, hyperthyroidism, incipient tuberculosis, relaxation of the sacroiliac joints and other postural defects with consequent muscular and ligamentous strain, etc.

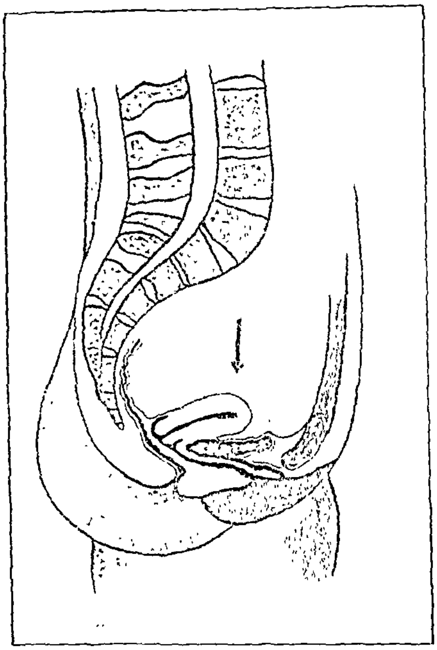

Fig. 1—Normal acute angle between the uterus and vagina. Intra-abdominal pressure, exerted from above, closes the vaginal slit firmly, thus preventing prolapse.

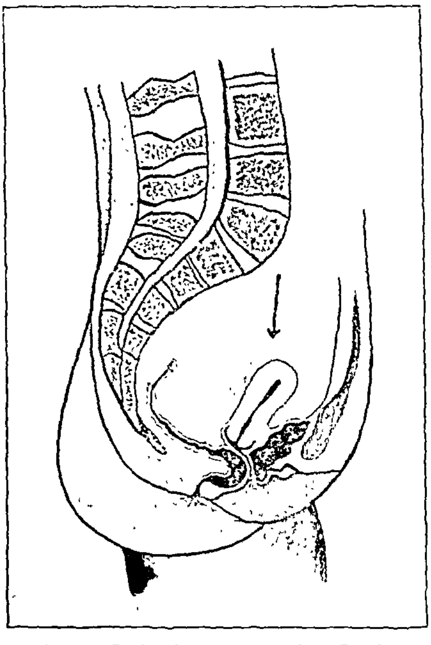

Fig. 2.—Cystocele and rectocele. Cervix permitted to move forward by relaxed broad and sacro-uterine ligaments. When the foregoing occurs the uterus and vagina are in approximately the same vertical line. It is then just a question of time when the uterus will telescope into and through the vagina.

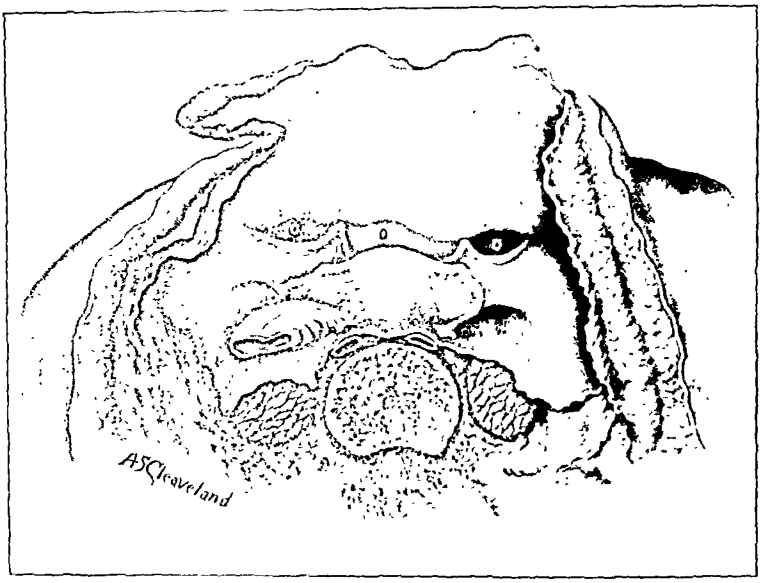

Fig. 3.—In common with other forms of transperitoneal suspension of the uterus, the Gilliam operation leaves firm bands of tissue stretching across the free abdominal cavity. R. L., round ligaments stretching across the free abdominal cavity, leaving three openings (O), through which it is possible for a loop of intestine to slip and become strangulated.

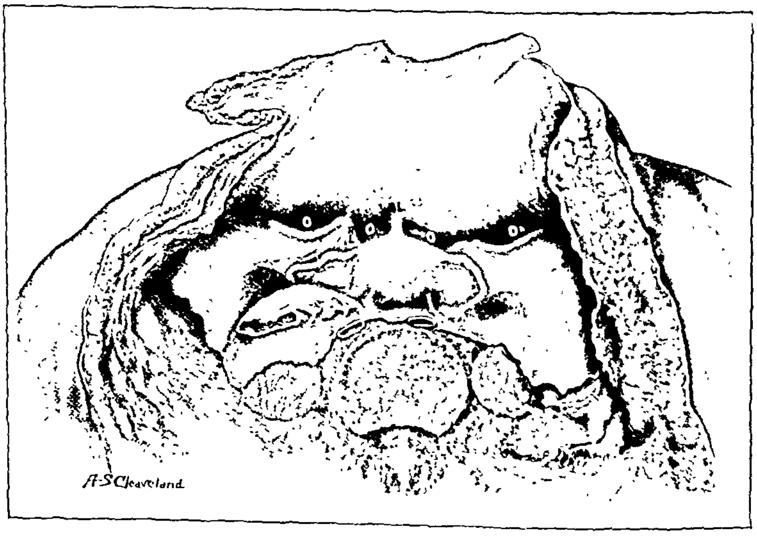

Fig. 4.—If by chance the ligaments should be overshortened and the fundus held in contact with the abdominal incision, the two surfaces become adherent. A suspensory ligament would be added and we would have four openings through which an intestine might slip and become strangulated. R. L., overshortened round ligaments and resulting suspensory ligaments (S. L.) which stretch across the free abdominal cavity, leaving four openings (O) through which an intestine might slip and become strangulated.

The medical profession and womankind owe a lasting debt of gratitude to Drs. Reynolds, Lovett, Goldthwaite and others for demonstrating the frequency with which backache is due to postural defects and rendering it easy to differentiate between the several types of pain.

Our chairman, Dr. Clark, has wisely emphasized the importance of making an itemized record of the several disease conditions affecting the individual patient; of the percentage in which they contribute to her discomforts, and of the extent to which each may *probably* be relieved by the proposed plan of treatment.

In this day of safe surgery, many people expect too much from operations and one will reduce the frequency and degree of disappointment if he strives to tell the individual patient beforehand just which of her discomforts may *not* be relieved by the operation. This enables the patient to decide judiciously regarding a plan of treatment.

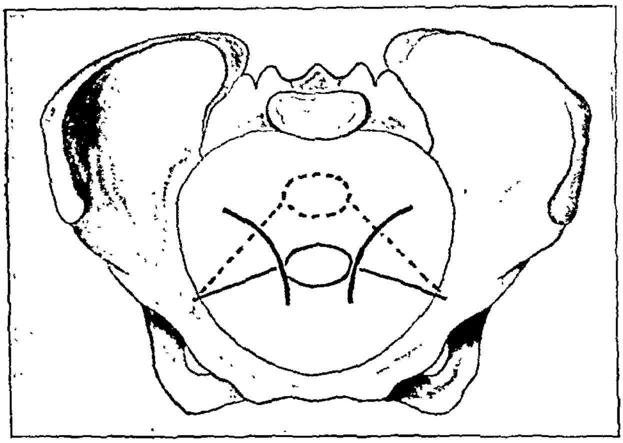

Fig. 5.—Heavy straight lines indicate normal direction of round ligaments. Dotted lines show the slight degree of stretching which will permit the uterus to become retroverted.

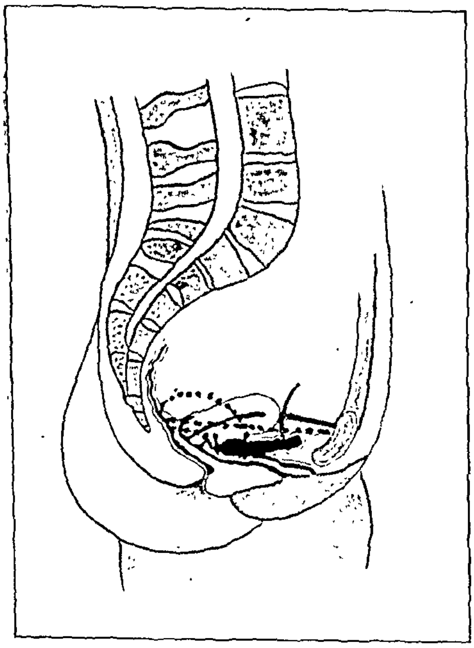

Fig. 6.—Heavy lines represent the shortened round ligament, which is directed forward. Dotted lines represent the marked stretching of the transplanted round ligaments that must take place before retroversion can occur.

OPERATIVE CORRECTION

It is needless to review here the evolution of the various procedures or to enumerate the several operations and modifications which hold the uterus forward. Each of the several recognized avenues for surgical correction has its advocates who have modified the following types of operation:

1. Inguinal shortening of the round ligaments (Alexander, Edebohls, Martin, Goldspohn).
2. Vaginal fixation of the uterus and vaginal shortening of the round ligaments (Goffe, Schuching, Duhrssen, Maskenrodt, Vineberg, Reed, Wertheim).
3. Intra-abdominal shortening of the round ligaments (Polk, Wylie, Dudley, Mann, Bissell, Morris, Baldy).
4. Attachment of round ligaments posterior to the uterus (Webster and Baldy).
5. Attaching the uterus to the anterior abdominal wall firmly, loosely, indirectly (Kelly, Fowler, Martin, Dorsett).
6. Transperitoneal shortening of the round ligaments (Olshausen, Ferguson, Beck, Gilliam, Martin, Campbell, McGannon).
7. Retroperitoneal shortening of the round ligaments (Ferguson, Noble, Simpson, Montgomery, Mayo, Peters, Barrett).
8. Shortening of the sacro-uterine ligaments through the abdomen or vagina (Bovée, Bishop, Stoner, Young).
9. Transverse attachment of the base of the broad ligaments in front of the cervix.
10. Intraperitoneal shortening of the round and broad ligaments (Coffey).

The uterus may be held forward by any one of several satisfactory methods. In order that it may remain in its normal position, it is necessary to maintain, to a considerable degree, the functional value, first, of the pelvic floor; second, of the supporting ligaments which radiate about the cervix; and third, of the round ligaments which act as guy-ropes. I take it that correction of mechanical defects of any of these structures constitutes an essential part in the several operations considered in this symposium.

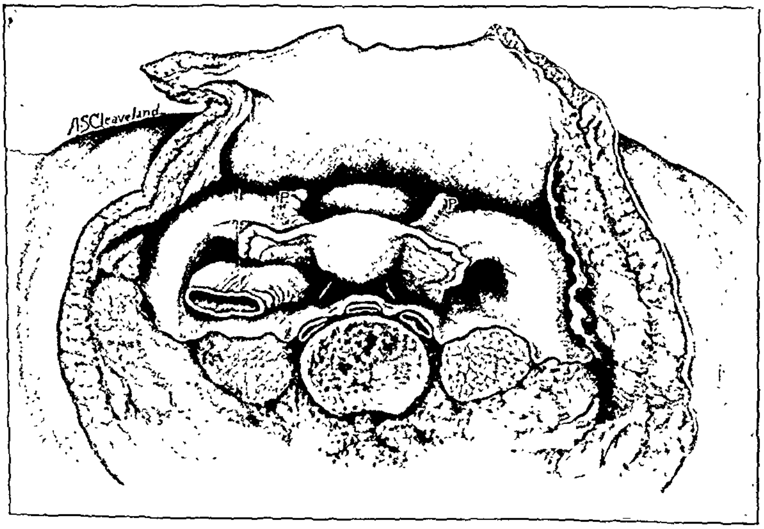

Fig. 7.—Uterus held in normal position by ligaments shortened and directed forward behind the parietal peritoneum (P).

The principles of safe and effective correction are simple. They not only take into consideration the normal position of the genital organs and the mechanism of displacements, but also the existence of other pelvic viscera (intestines, bladder, ureters) and the accidents common to them. The value of an otherwise satisfactory operation may be impaired by a considerable percentage of failures; by interfering with the function of reproduction; by causing considerable pain; by leaving bands of adhesions stretched across the free abdominal cavity; by entailing too great a risk to life or by frequently substituting other pathologic conditions which are themselves a source of considerable inconvenience.

It has always seemed to me that when skill, technic, facilities and other conditions justify elective operations, the mere fact of opening the abdomen does not necessarily entail serious risk. When the abdomen is opened, one can occasionally detect and correct associated troubles which would otherwise continue to cause discomfort. For these and other reasons, I am inclined to look with favor on the operations which open the abdomen in the mid line, thus making it possible to investigate all areas of discomfort.

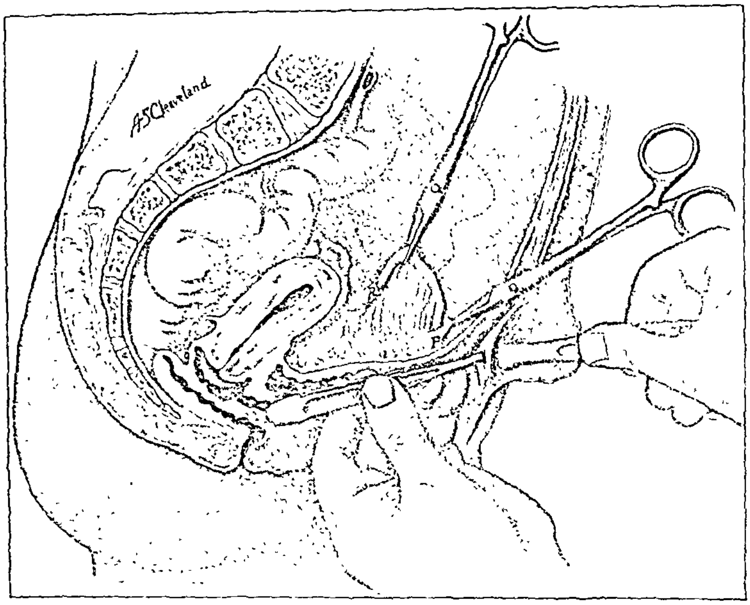

Fig. 8.—First step in retroperitoneal shortening of round ligaments. Landmarks are fixed by guide forceps preparatory to passing curved forceps in manner suggested and practiced by Drs. Charles H. Mayo and Barrett. R. L., round ligament grasped about 1½ inches from uterus. P., parietal peritoneum overlying internal ring picked up, as suggested by Dr. S. A. Chalfant.

At the time the Gilliam operation was first proposed, I was much impressed by the fact that if considered from the standpoint of the genital tract alone, it was simple and based on effective mechanical principles. The strong part of the round ligaments was used.

The ligaments were directed forward thereby giving them greater retaining power. The effect of that manner of attaching the ligaments was not to suspend the uterus, but to keep the fundus from rising and describing its backward arc of a circle.

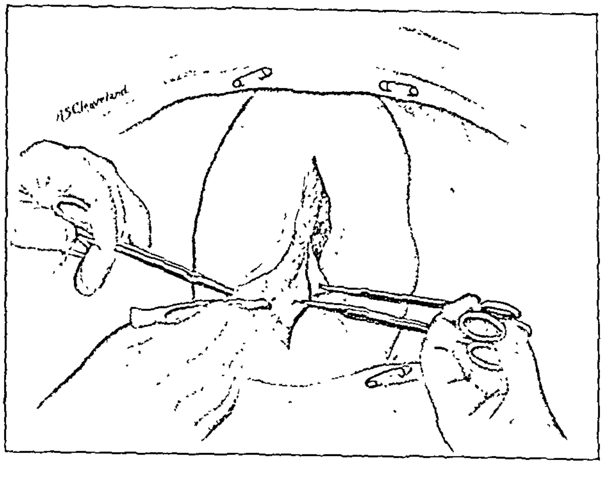

Fig. 9.—Second step: The skin is retracted and the fascia punctured about 1½ inches to the side of the lower angle of the incision.

The shortened ligaments would undoubtedly undergo the same changes of hypertrophy and involution common to normal ligaments in the course of gestation and the puerperium. Thus far the operation was ideal.

But in common with other forms of transperitoneal suspension, firm bands of tissue were stretched across the free abdominal cavity.

If by chance the ligaments were overshortened, and the fundus of the uterus held in contact with the abdominal incision, the fundus would become adherent.

A suspensory ligament would be added, and we would then have four openings through any one of which it seemed possible an intestine might slip and become strangulated.

It occurred to me at that time, as doubtless it did to many others, that if this possible source of danger could be avoided, the operation would be well-nigh ideal. At the Cincinnati meeting of the Southern Surgical and Gynecological Association in November, 1902, three papers were presented, each describing a method of utilizing the strong points of the Gilliam operation but obviating its dangers by effecting the shortening and transplantation beneath the parietal peritoneum. The first of these papers was read by Dr. A. H. Ferguson of Chicago; the second by Dr. George Noble of Atlanta, and in the third, I presented a preliminary report regarding the technic of a similar retroperitoneal operation.

The underlying principles of my operation were then described as follows:

> It consists essentially of changing the course of the round ligaments from a transverse to nearly an anteroposterior direction; in shortening the round ligaments so as to leave the distal end slack; the proximal end being used to control the movements of the uterus; finally, and especially, in effecting these changes beneath or by puckering the *parietal peritoneum*, thus leaving no bands of adhesions and no pockets which may strangulate an intestine. These principles have commended themselves to me as being mechanically and sur-

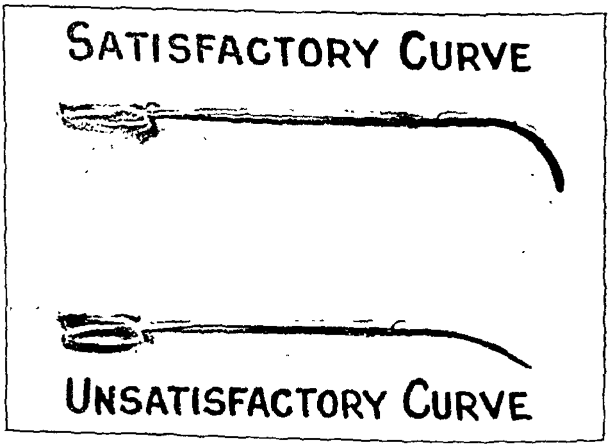

Fig. 10.—Forceps of satisfactory and unsatisfactory curve.

gically correct. Varying details of technic will readily suggest themselves to the operator.[1]

That this observation of eight years ago was fully warranted is shown by the subsequent publication of a considerable number of modifications of the three operations proposed at that meeting.

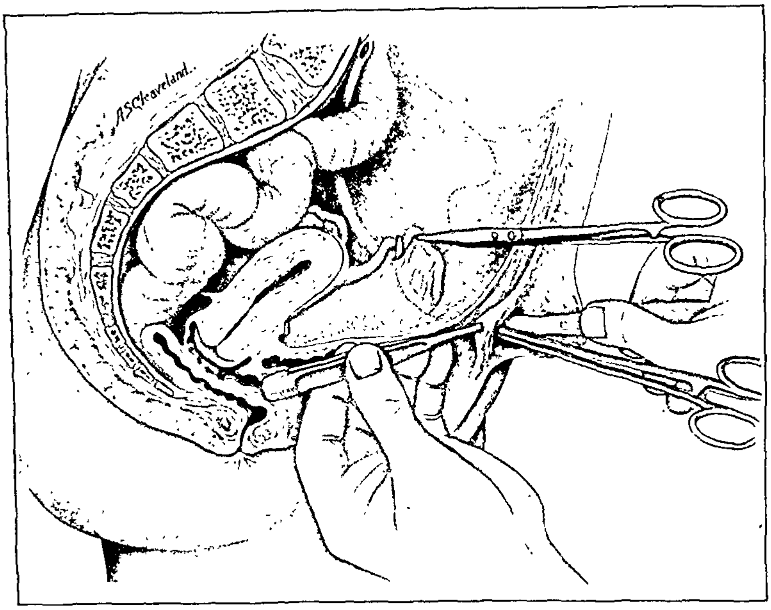

Fig. 11.—Third step: The forceps of proper curve, having passed through the fascia and obliquely through the rectus muscle, skirts beneath the parietal peritoneum to the internal abdominal ring, where it passes between the layers of the broad ligament and follows the course of the round ligament to 1½ inches of the uterus. At that point it penetrates the peritoneum, entering the peritoneal cavity for the first time, and then grasps the round ligament proximal to the guide forceps. (G. F.).

TECHNIC

My own technic has undergone several minor changes but has gradually settled down to that which we have employed for several years and considered safe, to a high degree effective, and as free as any abdominal operation of any kind can be, from the risk of adhesions. It has no bands stretching across the free abdominal cavity and carries no essential danger of strangulation. Except in two cases, it has caused no dragging sensation during pregnancy, or at any time, except during the first few days of the healing process.

Notable modifications have been made by Dr. Montgomery, Dr. Charles H. Mayo, Dr. Barrett and others. The operation as it now stands is a composite one. It consists in the following steps:

1. A median abdominal incision is made.
2. The round ligament is caught 1½ inches from the uterus and the parietal peritoneum at the point of the internal inguinal ring (Fig. 9).
3. The skin is retracted and the fascia punctured about 1½ inches to the side of the lower angle of the incision (Fig. 10).
4. A forceps of proper curve passes through this puncture, obliquely through the rectus muscle, following the method of Dr. Charles H. Mayo, and enters the broad ligament at the internal ring. It then continues to pass beneath the peritoneum and by the side of the round ligament until it reaches the hemostat holding the round ligament.
5. The curved forceps then penetrates the peritoneum and grasps the round ligament. The free margin of peritoneum is held by a hemostat during the next step.
6. The curved forceps is drawn out bringing the round ligament through the tunnel it has made.
7. The round ligament is then fastened and suspended just beneath the fascia by a linen thread which closes the rent in the fascia and at the same time holds the ligament firmly. The same process is repeated on the opposite side.

Some features and variations in technic and subsequent care which deserve comment are the following:

1. The ligament should not be attached to the upper surface of the fascia. Any permanent perforation of the fascia invites hernia.
2. The operator should actually see that his suture attaches the ligament to the fascia rather than to the fat overlying the fascia.
3. If the round ligaments are caught too near the uterus, or if they are fastened together in the mid line (either above or below the fascia), the uterus will be held in contact with the line of incision and a suspensory ligament will form. In one of my early cases that happened. The intestine became adherent, slipped behind the suspensory ligament (which should never exist) and annoying cramps followed, requiring operation.

RESULTS

1. *Mortality.*—I have done this operation with modifications, and in connection with necessary plastic and other work, about 400 times. There have been two deaths (in complicated cases), giving a mortality of 0.5 per cent. In about 70 per cent. of these cases, the appendix, tubes and ovaries, or adhesions required attention. During the last few weeks, I have gained definite information regarding about 75 per cent. of the patients. Regarding the other 25 per cent., either nothing has been heard from them or their physicians,

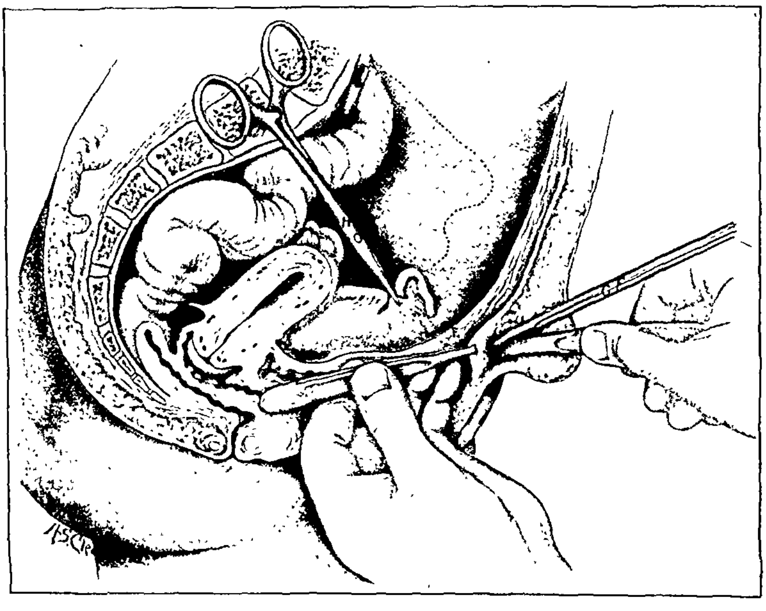

Fig. 12—Fourth step: The margin of peritoneal wound having been caught by hemostatic forceps (H), the curved forceps (C. F.) grasps the round ligament. By withdrawal of the curved forceps the round ligament is drawn out through the canal made by the forceps.

---

or else the doctor has reported that his information is neither recent nor exact. These facts have been obtained in two ways: first, from the medical attendants who have recently seen and examined the patients; and second, from my own notes made at the time of recent examinations. This inquiry includes:

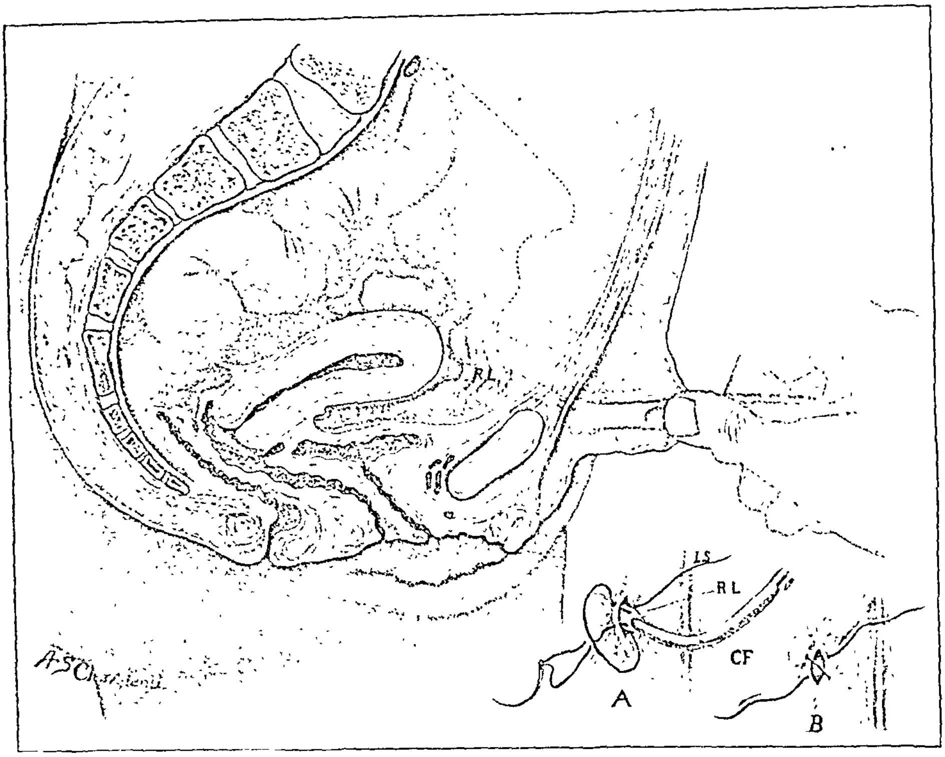

Fig. 13.—Final step: The round ligament (R. L.) is suspended beneath the fascia by a linen suture (L. S.) which also closes the rent in the fascia. The same process is repeated on the opposite side. Method of fastening shown on the margin.

2. *The Present Position of the Uterus.*—In two cases the uterus is known to be retroverted but without discomfort. Three or four uteri with congenital defects are about in the long axis of the body. Four with prolapse are known to have the fundus forward, but the cervix was not held well back by the plastic operations and shortening of the sacro-uterine ligaments. In three cases after delivery the uteri were back at about the sixth week, but were permanently corrected by the temporary use of pessaries. In all the other cases, that is, in more than 97 per cent. of those heard from, the uterus is in the normal position.

3. *Pregnancy.*—For various reasons (patients unmarried, widows, passed menopause, operation required removal of one or both adnexa, etc.), 40 per cent. of those heard from would not be expected to conceive. Of the remaining one hundred and eighty patients heard from, forty-five have conceived. One patient is now normally pregnant three months; one patient is now normally pregnant four months; two patients are now normally pregnant six months; two patients are now normally pregnant eight months, and one patient is now normally pregnant nine months.

Nine have aborted; four had aborted before; two of them probably had syphilis; in two no cause was known by the attendant. Three of these also bore one child. One had an ectopic gestation. Twenty-three bore one child at the end of normal pregnancy. Three of these also aborted once each. One of this number is reported to have died of puerperal infection seventeen days after a normal delivery. Five have had two children at the end of normal pregnancies.

4. *General Health.*—This has been very markedly improved or completely restored in 82 per cent.

Little or no improvement, 15 cases, 5 per cent.

Somewhat improved, 38 cases, 13 per cent.

Markedly improved, 128 cases, 43 per cent.

Completely restored, 117 cases, 39 per cent.

5. *Local Discomforts.*—These were very markedly or completely relieved in 84⅔ per cent.

Little or no improvement, 10 cases, 3⅓ per cent.

Required second operation for cystic ovaries after which relief was complete, 6 cases, 2 per cent.

Somewhat improved, 28 cases, 9⅓ per cent.

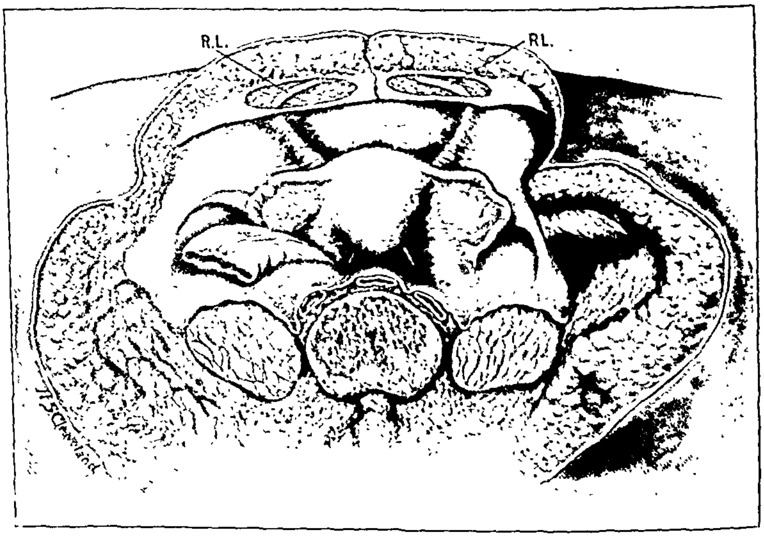

Fig. 14.—Retroperitoneal course of the round ligaments fastened beneath the fascia. P., folds of peritoneum covering the round ligament. R. L., round ligament as it lies in its oblique course through the rectus muscle and attached to the under surface of the fascia.

Decidedly improved, 72 cases, 24 per cent.

Completely relieved, 182 cases, 60⅔ per cent.

6. *New Local Discomforts.*—Here inquiry was especially made regarding dragging sensation in the new course of the ligaments. New discomforts were noted

in two, or less than 1 per cent.; *no* new local discomforts in 296, or about 99 per cent.

My percentage of partial or complete failure to hold the uterus forward has been about 2 per cent. No round-ligament operation alone will be uniformly successful under the following conditions:

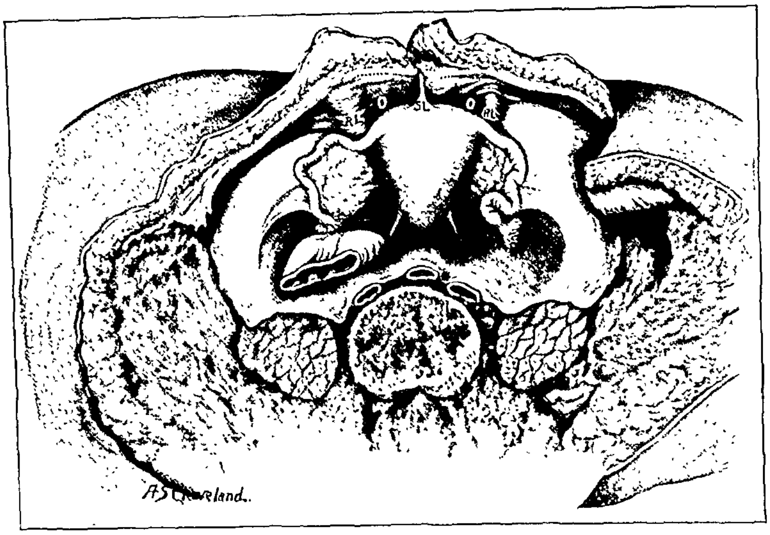

Fig. 15.—If the round ligaments are caught too near the uterus or if they are fastened together at the mid-line (either above or below the fascia) a suspensory ligament will likely be formed. Dotted lines show the retroperitoneal course of round ligaments which are fastened together in the mid-line S. L., which is the dangerous suspensory ligament so likely to form if this error is made.

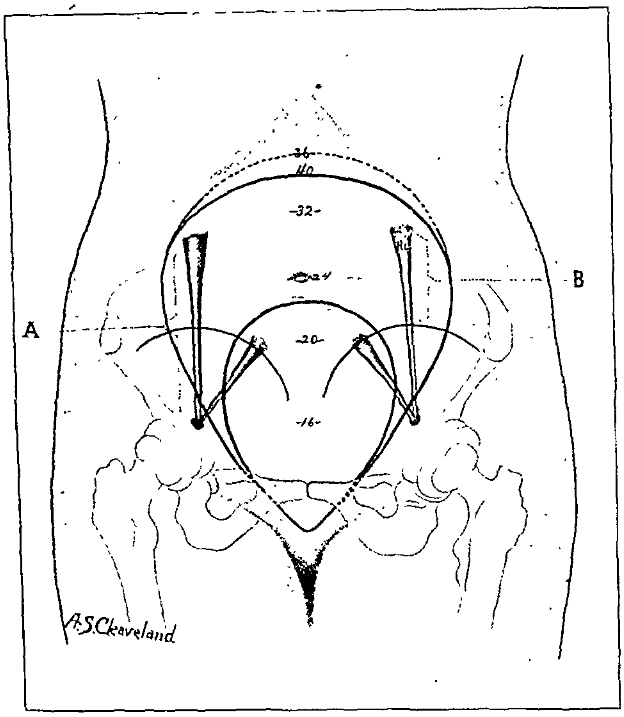

Fig. 16.—Immediately after delivery the uterus is markedly reduced in size and length. The length of the round ligaments is gradually reduced. For days they are long enough to permit the uterus to fall back into the hollow of the sacrum. If it remains back during the puerperium, the ligaments will be *permanently* stretched. A, total length of round ligament at the beginning of labor. B, excess of ligament at the end of labor.

1. When the ligaments are very delicate. I have had one failure due to this cause.

2. When the congenital attachment of the bladder is low and that of the sacro-uterine ligaments is high. This defect must also be corrected. I have had three or four partial failures due to this cause.

3. When the sacro-uterine ligaments and the base of the broad ligaments have been very much stretched, giving a decided prolapse. These defects should also be corrected (as, of course, the underlying lacerations). I have never had difficulty in keeping the fundus forward, but I have occasionally had an imperfect result because my attempts at shortening the sacro-uterine and the broad ligaments were not always perfectly satisfactory. I have knowledge of four cases of this kind.

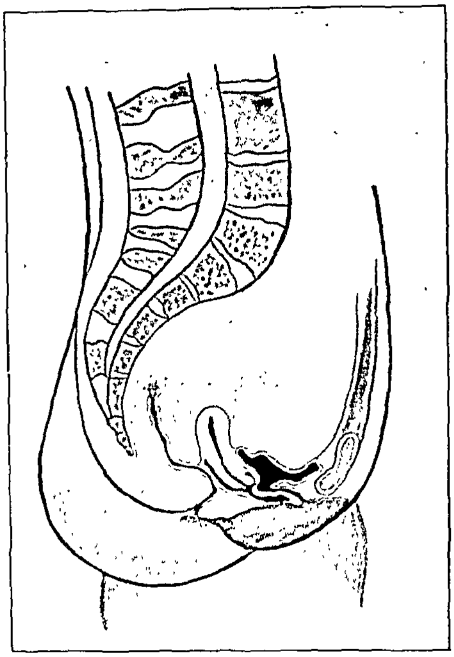

Fig. 17.—A low attachment of the bladder to the cervix, and a high attachment of the sacro-uterine ligaments. This faulty leverage must be overcome to ensure the success of any corrective measures.

The ligaments undergo the normal course of hypertrophy and involution during pregnancy and the puerperium. It is attended by slightly less risk of post-partum retroversion than follows delivery where the uterus has never previously been misplaced. This less risk is due to the anterior direction of the ligaments. Puerperal retroversions are easily and permanently corrected by the temporary use of pessaries. It, accordingly, is the imperative duty of the obstetrician to see that every uterus is in its normal position for at least three months after delivery, whether there has been previous trouble or not.

1112 Bessemer Building.

Massage in Neurasthenia.—The patients in whom massage is of most value are those feeble and emaciated individuals, asthenic in every respect, tired with the slightest effort, afflicted with atonic forms of dyspepsia in their most extreme degrees, often with flabby toneless hearts, low blood-pressure, anemic and incapable of the slightest mental exertion. The methods most suitable to neurasthenic patients are firm stroking or effleurage and kneading movements or pétrissage, the slapping, percussive and vibratory motions being omitted at first entirely, though vibration may soon be adopted for the abdomen, where it is especially useful in stimulating the intestinal muscle and the portal circulation. The mark of good massage is that the patient should feel rested and inclined to sleep, and should have a pleasant sense of warmth and comfort.—C. W. Buckley in the *Practitioner*.

THE TECHNIC OF THE EXAMINATION OF ESOPHAGEAL LESIONS*

H. S. PLUMMER, M.D.
Physician to St. Mary's Hospital
ROCHESTER, MINN.

About 300 esophageal cases which have come under observation during the last four years have been studied not only with a view to the establishment of a correct diagnosis and productive therapeutics for the individual case, but also with the idea of determining the relative value of the clinical and technical findings. I wish in this paper to consider briefly those points which contribute to obtaining definite technical data safely.

The clinical examination is of the utmost importance not only for its intrinsic value, but as a guide to the succeeding technical procedures. The more important features to be determined in esophageal diseases by the technical methods of examination are the existence, size and relations of pockets, dilatations and strictures, and the character of the esophageal wall, notably at the seat of narrowing.

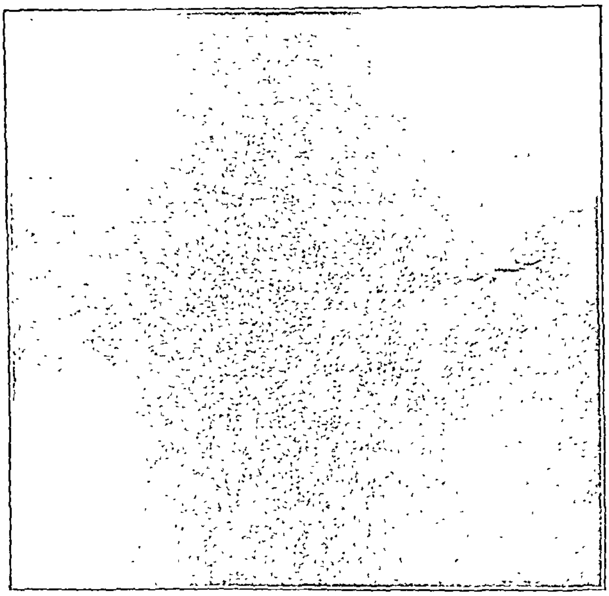

Fig 3.—Diverticulum of esophagus, from skiagraph.

The technical methods which have proved of especial value may be grouped under three heads, namely: roentgenography, esophagoscopy and the various methods of sounding.

Roentgenography discloses thoracic masses obstructing the esophagus by pressure from without and occasionally a good shadow may be obtained of an esophageal tumor. Its chief service is that of revealing the position, shape, size and relations of diverticula and dilatations when filled with bismuth mixtures. Diverticula as a rule give shadows which are characteristic (Figs. 1 to 6). The large dilatations which occur in the upper third of the esophagus above organic strictures can be distinguished from diverticula by a tail-like portion of bismuth extending downward from the bottom of the sac (Fig. 7). However, this may be absent. Passing a small sound on a thread quickly differentiates the two conditions. Most striking are the large, irregularly spindle-shaped shadows obtained in cases of diffuse dilatation of the esophagus following spasmodic and, infrequently, organic stricture at the cardia.

In cases of cardiospasm (Figs. 8 to 19) the lower extremity of the shadow is cone-shaped and its apex corresponds (Figs. 8 and 20) to the hiatus esophagi, while in cases of organic stricture the outline is irregular and terminates above the hiatus. In most instances the dilatation extends to the upper border of the manubrium and is constricted at the root of the lung. The dilatations occurring above organic strictures are, as a rule, of limited extent and in their lower portion irregular in outline (Fig. 21).

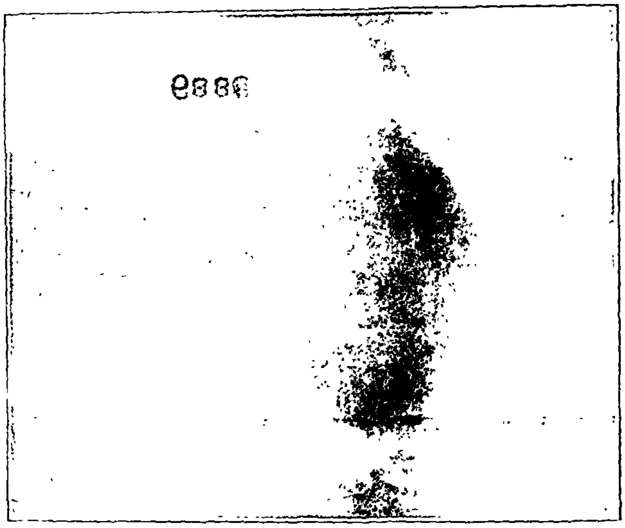

Fig. 4.—Diverticulum of esophagus, from skiagraph.

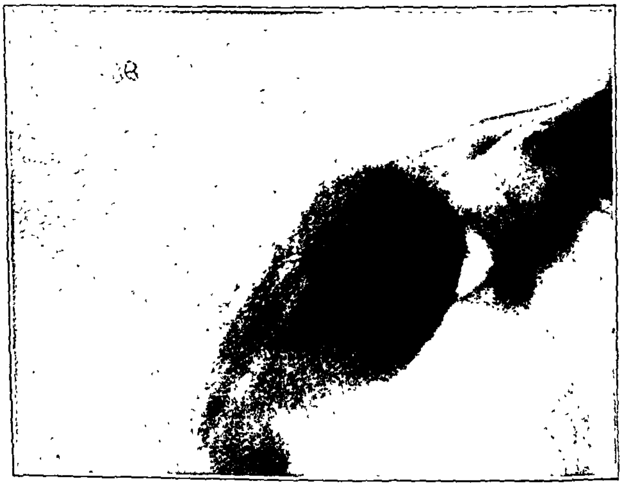

Fig. 5.—Diverticulum of esophagus, from skiagraph.

While the fluoroscopic pictures are interesting in studying both the normal and pathologic processes of deglutition, they add but little to the plate method in esophageal diagnosis. Mucilage of acacia has proved the most valuable vehicle in which to give bismuth. It adheres to the esophageal wall and can be readily washed out. The heavier bismuth meals and the rubber bags filled with bismuth do not give any advantage commensurate with the discomfort caused the patient. The bismuth capsule but rarely gives information not more easily obtained by other methods of examination. In patients complaining of slight or questionable dysphagia a delay in the passage of the bismuth may indicate grounds for an esophagoscopic examination.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-First Annual Session, at St. Louis, June, 1910.

* The illustrations accompanying this article were so numerous that part of them have been omitted because of lack of space. The entire article appears in the Transactions of the Section and in the author's reprints.

In esophageal work, success, from both the diagnostic and the therapeutic standpoints, depends largely on our ability to pass instruments through the esophagus.

Safety should be the keynote in esophageal technic. This is to be obtained by a clear conception of the way in which the force is being expended when introducing an esophageal instrument. The force is dissipated either in overcoming the friction of the staff on the wall of the passage or at the tip of the instrument. Obstruction at the tip is due either to pocketing or actual narrowing of the lumen in the canal. Safety resolves itself into the recognition of pockets and avoidance of undue pressure on an instrument which is pocketed.

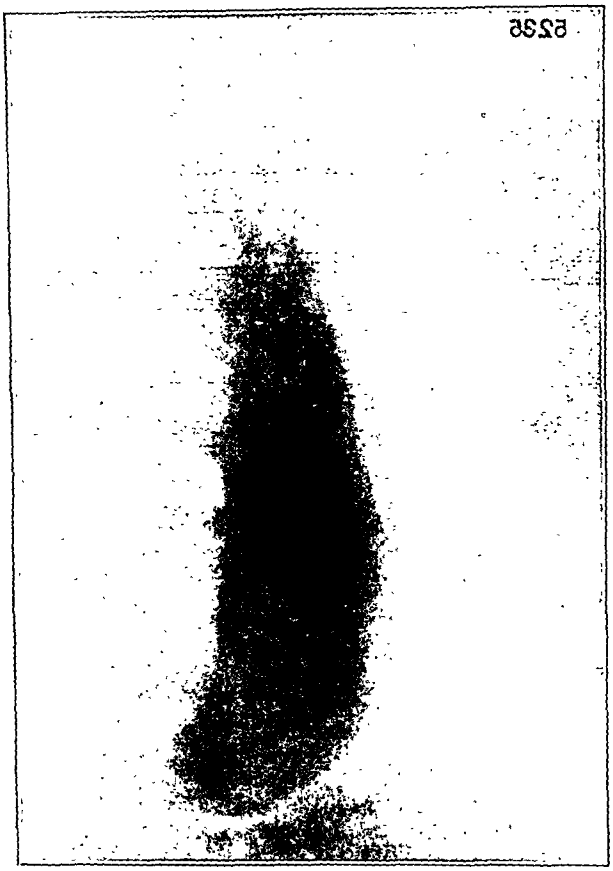

Fig. 8.—Diffuse dilatation of the esophagus in case of cardiospasm.

The tip of an esophageal instrument must be constantly under the guidance of vision or must follow a guide in such a way as to make perforation of the esophageal wall impossible. Let us conceive an instrument having the qualities of the finest silk thread at its tip, gradually merging into a rigid staff (Fig. 22). With patient persistence the thread could be passed through any patent esophagus and, if tension were maintained on the thread, the staff could be introduced into the stomach. This is mentioned to call attention quickly to the principles involved in successfully and safely introducing esophageal instruments. Such departures from this hypothetical instrument are permissible, as the rigidity of the staff, tortuosity of the canal, necessary force, etc., permit, without invalidating the essential principles. The adaptation of Mixter's method of using a silk thread as a guide has proved of inestimable value. The patient swallows six yards of silk thread. This passes down through a sufficient number of coils of intestine to prevent its withdrawal on being pulled taut.

With the whalebone staff and olive passed on a silk thread (Fig. 23*b*) we may locate pockets, determine their depth, measure the diameter of strictures, divulse them and estimate the rigidity of the esophageal wall at the seat of narrowing.

Only sufficient force to detect obstruction is permissible in advancing an unguided esophageal sound. With a silk thread that degree of force may be used which is short of carrying the thread out of its course and through the esophageal wall, or of endangering the esophagus by longitudinal traction, or of splitting the esophagus by a dilating wedge. If sufficient obstruction is encountered to make it seem possible that the thread might be carried out of its course, a piano wire (Fig. 23*c*) should first be passed on a thread and the olive passed on the wire. With the wire in place the possibility of introducing a sound is assured. When passing an olive on the wire, tension on the thread should be maintained to avoid any possibility of the tip of the wire penetrating the wall of the stomach or esophagus. Figures 24 and 23*d* show the distal portion of a piano wire guide and carrier for working the wire through a tortuous cicatricial stenosis on a thread. Various sizes of piano wire may be used and its flexibility further varied by the amount of wire exposed.

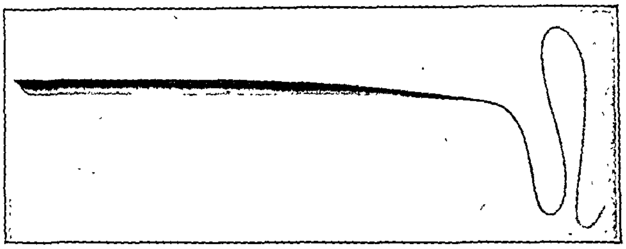

Fig. 22.—An ideal esophageal instrument, consisting of fine silk thread gradually merging into a more or less rigid instrument.

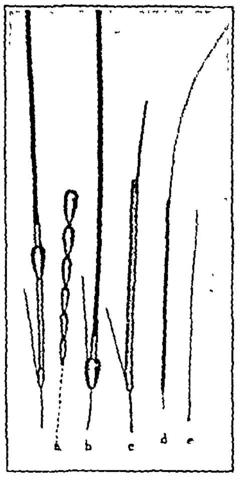

Fig. 23.—Various forms of esophageal sounds.

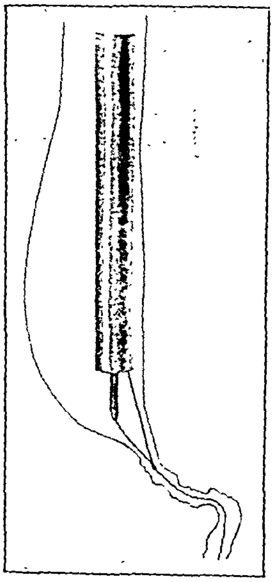

Fig. 24.—Piano-wire guide and carrier.

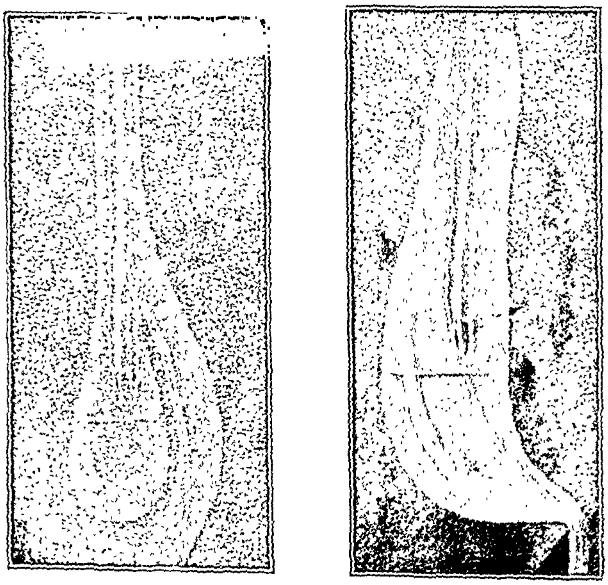
In the treatment of cicatricial stenosis the wire guide is not often necessary after the first dilatation, and the thread may be dispensed with as soon as the smaller sizes of spindles will pass without encountering obstruction at the site of the stricture. Further dilatation is carried out with the sound shown (Fig. 23*a*); the flexible, spiral metal tip acts as a guide and the stricture is dilated with the olive inserted in the staff. In those dense, extensive strictures in which sufficient dilatation cannot be obtained by dilating with a spindle, I resort to a modification of Dunham's esophagotome, which utilizes Dr. Abbe's principle of cutting partially through the distended stricture by a string pulled back and forth.

Without going into the reasons it is sufficient to state that an unguided sound will, as a rule, be pocketed if an opportunity is present. When introduced on a taut thread the sound follows the axis of the lumen of the esophagus. By varying the tension on the thread, obstruction from pocketing, and obstruction which is the result of actual narrowing of the canal, may be distinguished. The elimination of pocketing permits a more accurate determination of the diameter of the lumen and the rigidity of the esophageal wall at the seat of narrowing. Figures 25 and 26 (also 27 and 28) illustrate the use of a sound in demonstrating the existence of a pocket, its point of origin and more dependent portion. The sound is first introduced into the diverticulum until obstruction is encountered; holding the sound in place, the thread is drawn taut. Traction on the thread will now lift the sound out of the esophagus sufficiently far to bring the olive to a level with the opening into the distal portion of the esophagus. Until this point is reached the sound cannot be advanced without relaxing the thread. The same procedure, using a metal-tipped stomach-tube stiffened with a whalebone staff, permits of obtaining the contents of a diverticulum, dilatation or of the stomach, with a definite knowledge of the location of the point of the tube and a certainty that it will enter the stomach (Figs. 27 and 28).



Figs 27 and 28.—Metal-tipped stomach-tube guided by a thread.

Crowding a sound out of a pocket, or out of a pocket and through a cardia or stricture much larger than the olive, may give the impression of having passed a narrow stricture with rigid walls. The more accurate determination of the diameter of the lumen of the canal and the rigidity of the esophageal wall at the seat of narrowing, which the elimination of pocketing permits, is well illustrated by lesions at the cardiac orifice.

The thoracic portion of the esophagus is placed nearly in the median line, but deviates to the left as it passes forward to the opening in the diaphragm. In passing an olive through the lower three inches of a normal esophagus the staff impinges on the left anterior wall and the olive is directed to the cardia by the left posterior wall. This portion of the esophageal wall presents an increasing degree of obstruction as it approaches a horizontal plane in cases of diffuse dilatation. The degree of obstruction encountered depends also on the stiffness of the staff, the size of the olive and the tonicity of the esophageal wall. A stiff staff has a tendency to penetrate the esophageal wall (Fig. 29*A*), while a relatively flexible staff conforms to the right posterior wall and the olive approaches the opening in the diaphragm at an angle with the axis of this portion of the esophagus (Fig. 29*B*). The rigidity of the esophageal wall and the ledge formed by the upper margin of the growth are also important factors in passing a sound through a carcinomatous cardia (Fig. 30).

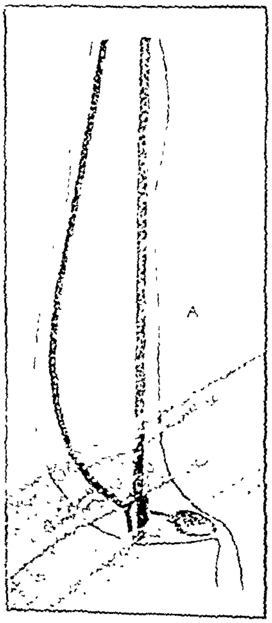


Fig. 29.

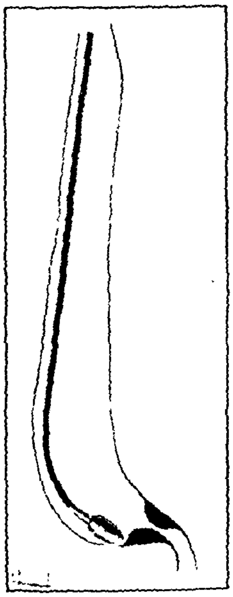

Fig. 30.

Fig 29.—Diagram of diffuse esophageal dilatation, showing danger from stiff staff (*A*), together with use of flexible staff (*B*).
Fig. 30.—Passing a sound through a carcinomatous cardia.

In cases of diffuse dilatation following cardiospasm it is frequently impossible to pass an unguided sound through the cardia with a degree of force that is safe (thirty out of sixty-five cases which have come under my observation), while a 15-mm. olive but rarely meets marked obstruction when passed on a thread. Decided obstruction of yielding character, followed by slight hemorrhage, is usually encountered when passing a carcinomatous cardia, while in benign cicatricial stenosis the smallest sizes of olive encounter an unyielding esophageal wall.

Leaving foreign body cases out of consideration, the most essential service of esophagoscopy is that of revealing the character of the esophageal wall. It is a relatively safe procedure in the hands of one who has acquired good technic. Safety lies in a clear conception of the way in which the force is being expended when introducing the instrument. Friction on the walls of the passage is an important element, as it makes advancement of the instrument jerky and obscures any fine sense of resistance at the tip of the instrument. I wish to call attention to Brunning's modification of Killian's esophagoscope (Fig. 31). It has a convenient and a sufficiently strong handle to permit of bringing the cardia into view, a light that rarely fails at the critical moment, a short upper section with a tip well adapted for easily passing the cricoid, and that eliminates friction in introducing a telescoping section through the lower portion of the esophagus. A satisfactory examination can, in the majority of cases, be made without an anesthetic in less than five minutes. In rare instances a guide becomes necessary to pass the cricoid, a ledge of mucous membrane, or a tortuous esophagus, the lumen of which is large enough to admit an esophagoscope. This guide must follow the lumen of the esophagus in such a way as to make perforation with its tip impossible. At its tip it should be sufficiently flexible to follow the lumen of the canal or a silk thread, and yet not double on itself. From its tip it should gradually merge into the rigid staff of the esophagoscope so as not to permit of any abrupt curve or ledge which might bruise or gouge the mucous membrane.

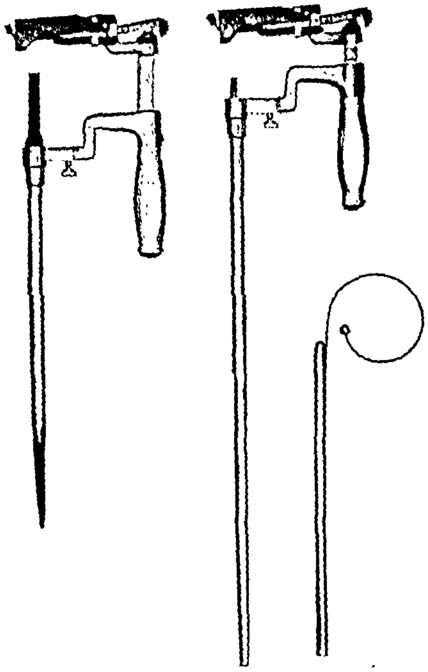

Fig. 31.—Brunning's modification of Killian's esophagoscope.

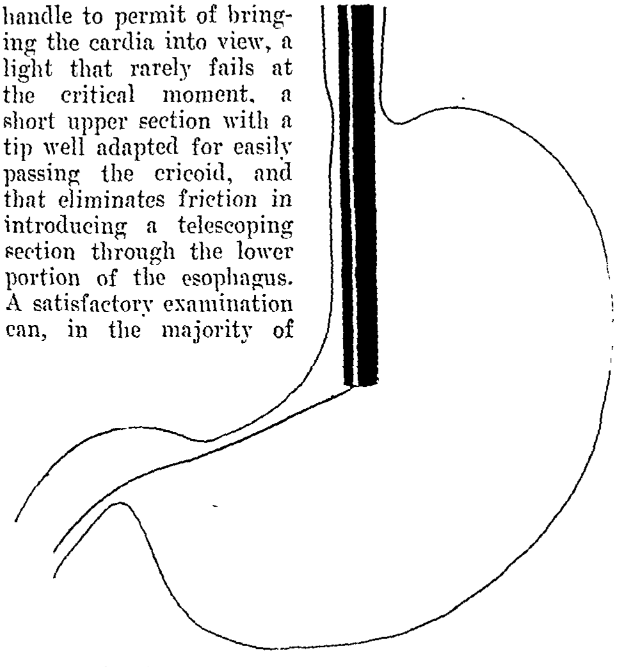

Fig. 37.—Thread used as a guide in gastroscopy.

In esophagoscopic work one of the chief drawbacks is the constriction of the esophagus above that portion of the esophageal wall essential to our knowledge. In about 35 per cent. of the cases of carcinoma, for instance, the mucous membrane is intact at the lowest point in the esophagus which can be brought under inspection. Figure 32 (also Fig. 30) illustrates an esophagoscope obstructed by a ledge formed by infiltration beneath an intact mucous membrane. A small esophagoscope may be introduced through a preceding one, with a guide, sufficiently far to bring the involved mucous membrane into view (Figs. 33 and 34). The elimination of friction by the first instrument introduced permits of safely carrying out this procedure in a good many instances.

Occasionally the thread is a valuable guide in following the course of the esophagus with the esophagoscope. To the experienced operator this is not of much advantage, except in cases of congenital malformation and in locating the slit-like opening into the distal portion of the esophagus in cases of diverticula (Figs. 35 and 36; also 23 and 24). When drawn taut the thread impinges on that margin of the distal opening of the esophagoscope toward the lumen of the esophagus. In direct gastroscopy, orientation is much facilitated in a similar manner (Fig. 37).

ABSTRACT OF DISCUSSION

DR. WILLY MEYER, New York: The method just advanced by Dr. Plummer is an extremely valuable addition to our resources for the diagnosis and treatment of esophageal troubles, especially of diverticula. It shows how we are able to make our diagnosis even in difficult cases. At the meeting of the American Surgical Association, recently held in Washington, Dr. Charles H. Mayo told us how he, on the basis of such a definite diagnosis, has been able to extirpate two pressure diverticula in the upper portion of the esophagus.

At the German Hospital of New York, Dr. De Witt Stetten, one of the adjunct surgeons, recently operated successfully in a case of this kind and published a very interesting analysis of esophageal diverticula. This class of diverticulum is a surgical disease. What I wish to emphasize is that it is also sometimes impossible in cases of large fusiform diverticula of the esophagus, as we meet them in consequence of cardiospasm of long standing, to get along with non-operative treatment. We know that if cardiospasm has existed for a long time the wall of the esophagus is very much distended, in the shape of a lamp chimney. In such a case I am sure that it is impossible to expect the esophagus, even with the cardia treated persistently by dilatation, to be amenable to reconstruction; the muscular layer of the esophageal pouch will not get back the power of thorough contraction so as to allow fluids and solids to pass easily down into the stomach. Often it is impossible to pass the contracted cardia with any kind of instrument or thread. In such cases operative procedures must be resorted to.

At the German Hospital in New York we recently had a patient, 45 years old, who had been sick for fifteen years with what was evidently a cardiospasm at the beginning. Later, in spite of treatment, the patient was unable to swallow anything. Even fluids were regurgitated after a little while. The patient had to be treated by rectal feeding. Soon gastrostomy had to be done. Careful diagnosis with the *x*-rays showed a stricture at the cardia, with a large fusiform dilatation above. The sound always was caught in the region of the cardia, and could be introduced with gentle handling for nineteen inches (sixteen inches is the average length down to the cardia). Still, with the cystoscope in the stomach, introduced through the gastric fistula, we could not see the sound. It was caught in the large esophageal pouch above the diaphragm. Therefore, basing our procedure in a patient absolutely averse to further instrumentation on the knowledge that such an esophagus cannot retract to proper size, we proceeded in the following manner: With the help of the lower half of Schede's incision through the skin and serratus muscle the left thoracic cavity was entered in the seventh intercostal space with differential pressure. The lung, which was tightly adherent to the chest wall, had to be loosened, and was then pressed upward and inward. With good illumination we found the large fusiform diverticulum covering three or four inches of the esophagus, as diagnosed, just above the cardia. It represented a large pouch. After division of the posterior continuation of the costal pleura the pneumogastrics were pushed aside and the left forefinger gradually worked around the pouch. A sound introduced from above was always caught posteriorly in a pocket near the spine. With the one hand in the thoracic cavity around the esophagus, the lower end of the sound could be guided and lifted upward with the other hand, so that it was made to pass through the cardia. I then made a plication or double fold in the esophagus by means of suture, in this way materially reducing the diameter of the fusiform dilatation in a length of three to four inches. At the end of the operation the esophagus was allowed to go back into its bed. To-day the patient is in good condition.

NOTE (Later).—At the end of June she is able to swallow everything without regurgitation.

DR. H. S. PLUMMER, Rochester, Minn.: Some sixty-five cases of diffuse dilatation of the esophagus have come under my observation, many of the patients being in the last stages of inanition, some of them right at the point of death. Many of them gave a history extending back over twelve or twenty years. I have not seen any case that was not readily, easily and completely cured by dilating the cardia.

TECHNIC FOR REMOVAL OF APPENDIX AND FIXATION OF CECUM*

C. A. ROEDER, M.D.
GRAND ISLAND, NEB.

THE APPENDIX

Although removal of the appendix is generally a simple matter and is attempted by the general practitioner as well as by the surgeon, it is too often followed by annoying symptoms which are generally due to adhesions. Therefore any technic that is simpler than the average and does away with the possibility of post-operative adhesions, is the one to be adopted.

Below is a procedure adopted by George Roeder and myself in the last 100 appendectomies, which is a sufficient number, I think, on which to base an opinion. It is simple, rapid and also safe, requiring on the average ten minutes from the time the incision in the skin is made until it is closed.

Its essential features are a single purse-string, fine linen suture which is not cut until the operation is finished (Figs. 1 and 2). The suture, in passing from one side of the mesentery to the other, passes through the external coat of the base of the appendix on its mesenteric border in order to embrace an artery that might run along the surface, which will be inside the purse-string after the crushed stump of the appendix is inverted; no area of cecum is ever uncovered by peri-

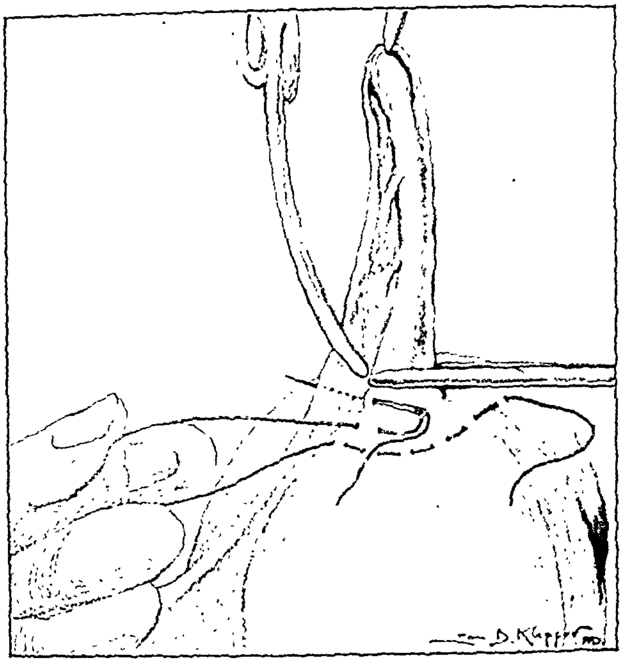

Fig. 1.—Appendix extended; crusher applied so as not to include any portion of the mesentery; artery forceps applied to the meso-appendix; purse-string suture passed through the external coat of the cecum, the needle taking a bite of the appendix through its external coat at its base on the mesenteric edge. The suture is then continued around on the other side, the loop being held by the assistant.

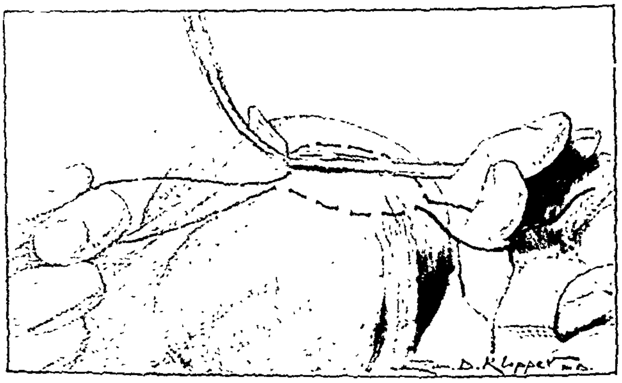

Fig. 2.—The appendix is cut flush with the crusher and the meso-appendix one-fourth inch above the artery clamp; the purse-string suture is shown completely encircling the appendix base. The crusher is now gently released and the stump is inverted.

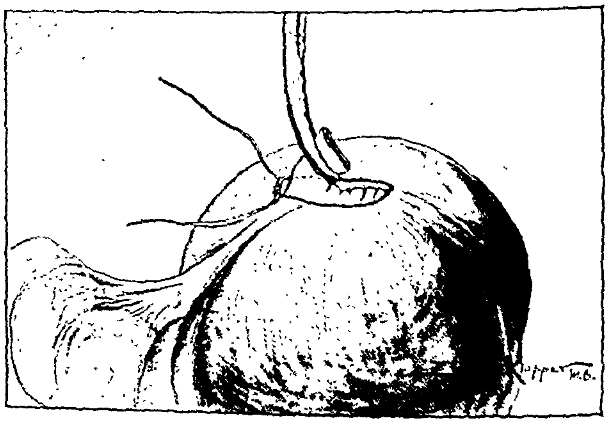

Fig. 3.—The appendix inverted; the clamp still on the mesentery; the purse-string suture is drawn together and its ends are being tied around the stump of the mesentery in the groove made by the clamp, which leaves a knob distal to it, preventing it from slipping off the mesentery and its artery.

toneum; this does away with suturing the peritoneum over the bowel as in other procedures. A second purse-string, continued from the first, inverts the stump of the ligated mesentery with its artery and buries the knot, leaving a perfectly clean peritoneum behind (Fig. 5). This second purse-string relieves tension on the first from post-operative gas, a valuable suggestion from the Mayo clinic.

We do not tie the stump; the procedure is entirely unnecessary with this method, and not without danger, as there would be a pocket formed, below by a ligated raw stump, and the purse-string above, inhibiting drainage into the bowel, which might be necessary for infected or necrosed material. Figures 4 and 5 illustrate further steps in the operation.

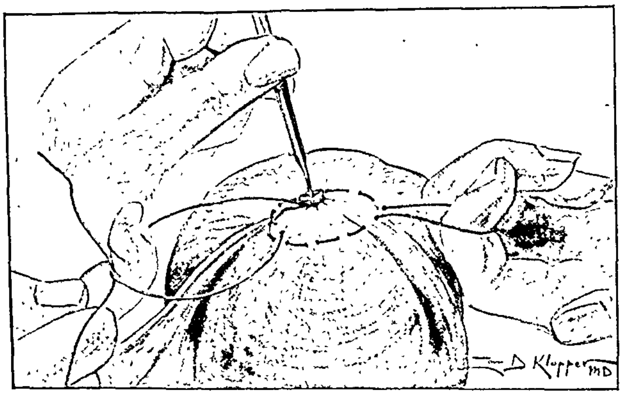

Fig. 4.—Meso-appendix tied over the point where the appendix has been inverted; no area of bowel uncovered by peritoneum. The original suture, uncut, is continued as a second purse-string suture, passing one-fourth inch beyond where it first entered the bowel and one-fourth inch internal. Note carefully the arrangement of the suture. When drawn it can readily be seen how the knot is inverted. The stump shown is the ligated meso-appendix.

In some cases a short mesentery is found requiring separate ligation, and here the stump of the mesentery is covered by peritoneum from the two layers of the cut mesentery.

This operation does not interfere with the action of the ileocecal valve, as there should be no tension on the meso-appendix when finished. The second purse-string is large enough only to cover the stump of the meso-appendix with the serous coat of the cecum.

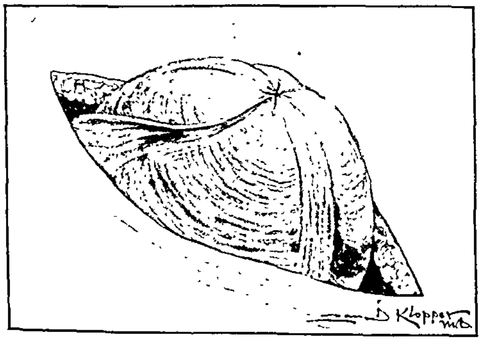

Fig. 5.—Operation completed; knot buried; remains of the meso-appendix are seen running across the cecum, with no area of bowel denuded and no portions of sutures exposed to the peritoneal cavity.

THE CECUM

The movable cecum, producing symptoms, we have anchored with excellent results by the following technic. The more dilated the pouch the more bites we take around its circumference. Without dilatation only one bite is taken.

The sutures (linen) which are inserted on the external wall in order to avoid ligating the vessels (which are in the inner layer of the mesentery), include all the coats but the mucosa, and no harm is done if they should happen to include the mucous membrane.

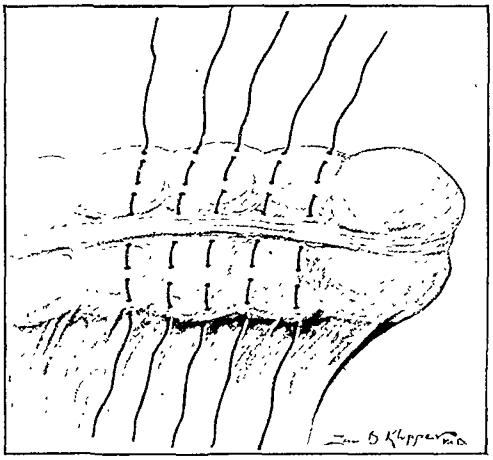

Fig. 6.—The cecum with its elongated mesentery; sutures placed. Note that the sutures have included the external longitudinal band, which gives them a firm hold. See conditions stated in text.

The sutures are then passed through the parietal peritoneum and fascia beneath, taking a bite about one-half an inch wide as close as possible to where the external coat of the mesentery of the cecum is deflected on to the abdominal wall. In this way the cecum swings from practically the same point, but the excursion is lessened. We use from three to eight rows of sutures one-half inch apart, depending on the size of the pouch and ascending colon, the degree of mobility, the age of the patient; the younger the patient the more fixation being required. The degree of constipation is another factor, as we have found often a very loose cecum in patients giving a history of constipation. Here we fix

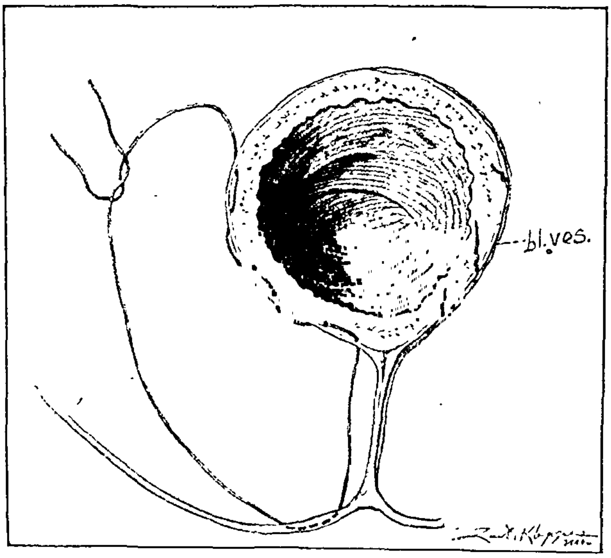

Fig. 7.—A transverse section; the suture passed but not tied. Note that the suture leaves the bowel about where the peritoneum does and takes a bite about where the latter is attached to the abdominal wall. The blood-vessels are on the other side and are never interfered with.

the cecum and half of the ascending colon to give the bowel a fixed point (Figs. 6 and 7).

The appendix is often kinked, requiring removal. The kink described by Lane in the ileum should be relieved by dividing the bands producing it and fixing the cecum high enough so that the ileum approaches it from below, or at least at a right angle.

OBSERVATIONS ON TWENTY-EIGHT PATIENTS TREATED WITH THE EHRLICH-HATA REMEDY (SALVARSAN)

B. C. CORBUS, M.D.
Assistant Professor of Genito-Urinary Diseases, College of Physicians and Surgeons, Medical Department of the University of Illinois
CHICAGO

Notwithstanding the fact that Ehrlich says that the preliminary stage has been closed, one receives the impression from the recent literature on 606 that there are many points still to be settled in almost every phase of the work with this new remedy especially in regard to its administration, prognosis, indications and by-effects. We stand at the beginning of our work; many questions need elucidation, and it is of general interest that results should be collected from many different sources.

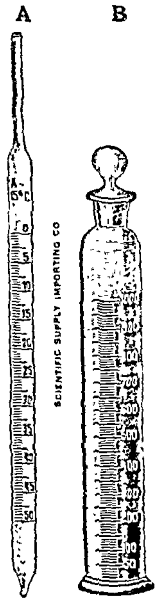

Fig. 1

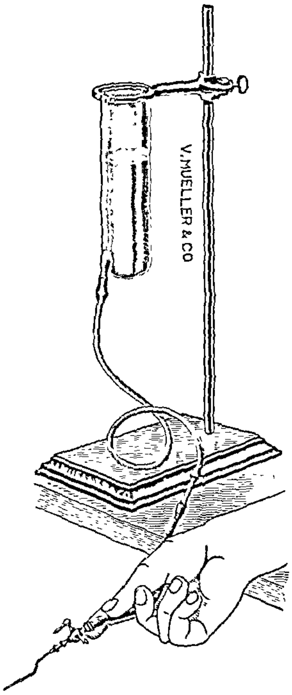

Fig. 2

Fig. 1.—Graduated pipette (A) and large 250 c.c. cylinder (B).
Fig. 2.—Intravenous apparatus.

The difficulty of following the technic according to the directions enclosed with salvarsan is apparent, for here one is told vaguely to use an intravenous method, a neutral suspension or an alkaline solution. At the present writing, the intravenous and the alkaline solution methods are the most popular in European clinics, but still each clinician is endeavoring to push his own method regardless of whether or not the other method is the superior.

From my personal experience with salvarsan (606) I believe that, while it is applicable in every case and attended by fewer symptoms afterward, the intravenous method, on account of the rapid elimination of the arsenic is greatly inferior to the intramuscular alkaline solution method of Alt and Lesser, and as a consequence should not be used in preference to all other methods. The same is equally true of the alkaline solution method.

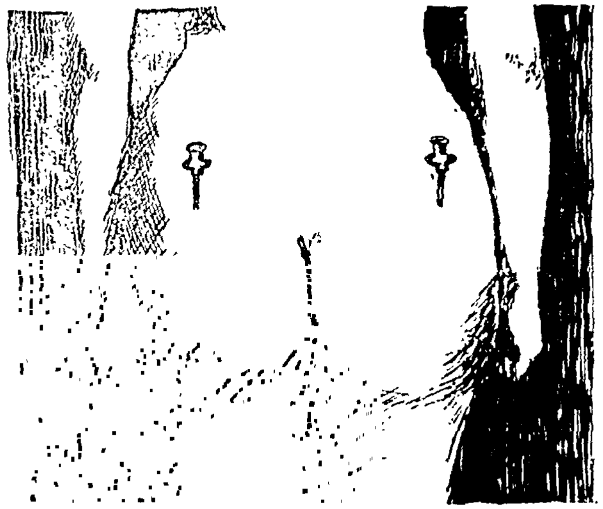

Fig. 3.—Site for injections.

Each case should be treated individually with special reference to the following points:

1. Duration of infection.
2. Severity of infection.
3. Condition and age of the patient.

In all early infections (by this I mean those that come under observation before the Wassermann reaction is positive) the intravenous method is especially indicated. Here subsequent treatments may be given the same way on an average of every ten days for three or four times. This form of treatment applied in such a case is ideal, as the solution in the blood-stream is able to act on the spirochetes with deadly effect. In my opinion, the value of this method decreases in direct proportion to the length of time of the infection, as in the later stages the spirochetes are so securely entrenched by the pathologic-anatomic lesions that the intravenous injection has only a minimum effect on the condition. This is borne out by Mickley[1] in Lesser's clinic. However, in paresis and in malignant lues, where quick action is desired, this is the only method that should be employed.

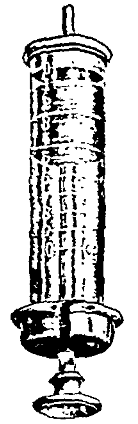

Fig. 4.—Record syringe.
Fig. 5.—Needle (21 gauge) used in Record syringe.

INTRAVENOUS TECHNIC

The instruments are one large 250 c.c. cylinder (Fig. 1, B), filter-papers, one funnel, one intravenous apparatus, like the accompanying cut (Fig. 2), one graduated pipette, (Fig. 1, A), and one stock bottle of normal sodium hydroxid solution (4 per cent.). The instruments and filter-paper having been previously sterilized (which may be accomplished for the latter by moist heat and later drying between sterile towels), also the ampoule of salvarsan and the file by immersion in alcohol; the ampoule is dried, opened with the sterile file and the contents poured into the cylinder. As this salt goes into solution very much more readily than the earlier supplies of the substance, it is not necessary to add any glass pearls to assist in the mixing. Fifteen c.c. of hot water are added; the hotter the water, the more quickly the substance will go into solution. Next normal sodium hydroxid solution is added, about 2 c.c., and shaken thoroughly. A precipitate occurs. Then sodium hydroxid solution is added, drop by drop, the solution being shaken after each additional drop until it is absolutely clear, care being taken not to add any excess of NaOH. Next distilled water is added up to 200 c.c. The whole is then filtered into the receptacle which accompanies the intravenous apparatus. Here the outlet is in the side of the cylinder, slightly above the bottom, forming a little receptacle that holds any foreign material that may get into the cylinder, thus ensuring a more perfect solution injected. It is not necessary to use normal saline solution, as the above solution is very nearly isotonic. Next, the arm is thoroughly scrubbed and a constrictor is placed above the elbow. After taking care that the solution runs through the tube and needle easily and that it is not above 98.6 F., and that the air bubbles are all extracted, the needle is thrust into the vein, great care being used not to puncture the vein except in one place, for any of the solution elsewhere than in the vein will produce a marked paraphlebitis. With the two-way cock attachment, it is easy to tell when one is in the lumen of the vessel, as the blood will come pouring out. Then it is an easy matter to remove the constriction, turn the cock, and send the solution into the vein. With the cylinder raised 28 or 30 inches above the patient's head, and with an 18 or 20 gauge needle the solution will pass in easily in about seven to twelve minutes.

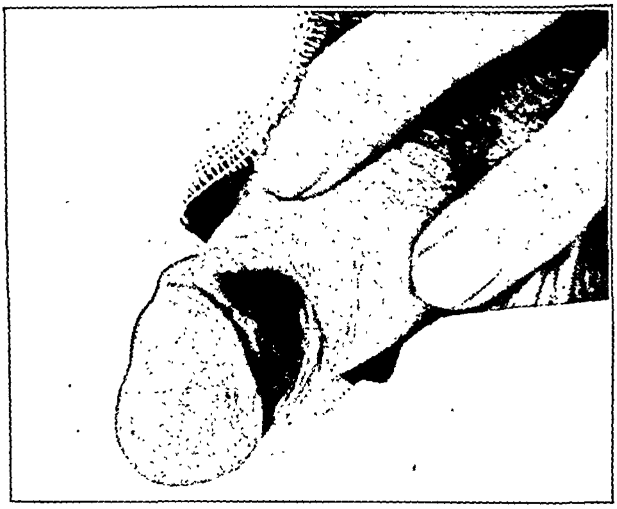

Fig. 6.—Indurated primary lesion, Nov. 3, 1910 (Case 1).

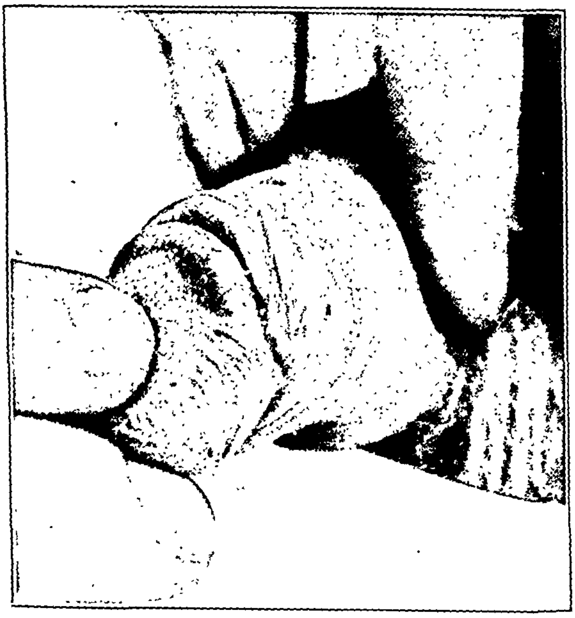

Fig. 7.—Healed lesion in 12 days, Nov. 15, 1910 (Case 1).

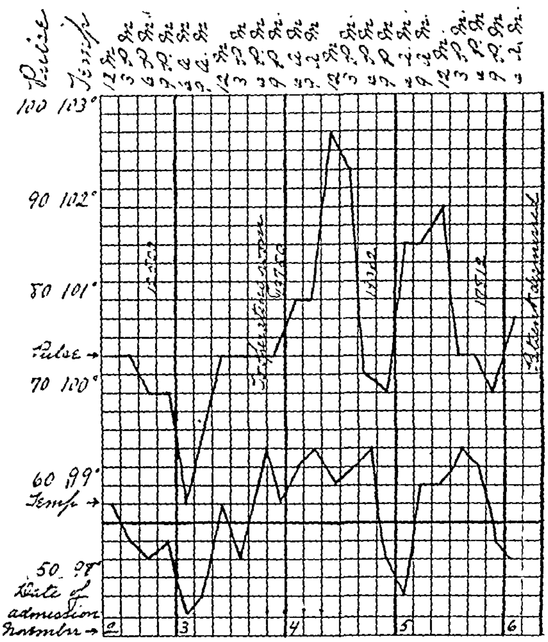

Fig. 8.—Chart showing pulse, temperature and leukocyte count of a case of primary lues (Case 1). This patient came under observation before the secondary eruption but after the Wassermann reaction was positive. The leukocyte count went to 19,062. This is the average in this class of cases. This patient has had two injections, the Wassermann becoming negative and remaining so after the fifth week.

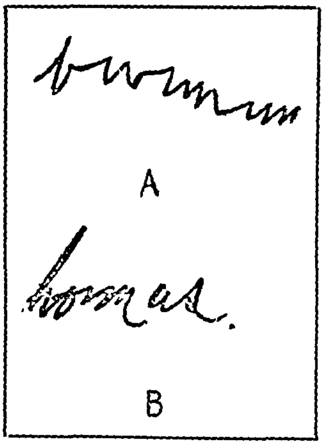

Fig. 9.—Handwriting of a patient with cerebrospinal syphilis occurring during the secondary manifestation (Case 4). A, portion of patient's name written by himself the day before injection, Oct. 17, 1910; B, same portion of patient's name written by himself two days after injection.

It is true that filtering the solution may seem to be superfluous, but often the salt agglutinates and there are small gelatinous-like particles that do not dissolve;

and again sometimes there may be some splintering of glass in opening the ampoule. Therefore, in order to carry this technic out in the best possible manner, it is necessary to have a perfect solution. When the solution has passed into the vein the wound is closed with a collodion dressing.

TECHNIC OF ALKALINE SOLUTION

The materials are: 15 c.c. graduated cylinder with glass stopper, tube of salvarsan and file, which have been previously sterilized with alcohol, one graduated pipette, stock bottle of normal sodium hydroxid solution and one 4-ounce beaker. It is best to sterilize the glassware with dry heat. The salvarsan is placed in a graduated cylinder with glass stopper; 15 c.c. of hot water are added immediately; the solution is shaken vigorously until every particle of the salt is dissolved; then 2 c.c. of normal sodium hydroxid solution are added; a precipitate occurs. Then the sodium hydroxid solution is added drop by drop, being shaken vigorously after each addition, until the solution becomes perfectly clear, avoiding any excess of NaOH; then hot water is added enough to make 20 c.c. of the total solution. Then 10 c.c. of this solution are injected deeply into the buttocks on either side (Fig. 3), care being always taken to cleanse the parts with soap, water and iodin, and to cover them after the injection with absorbent cotton and flexible collodion.

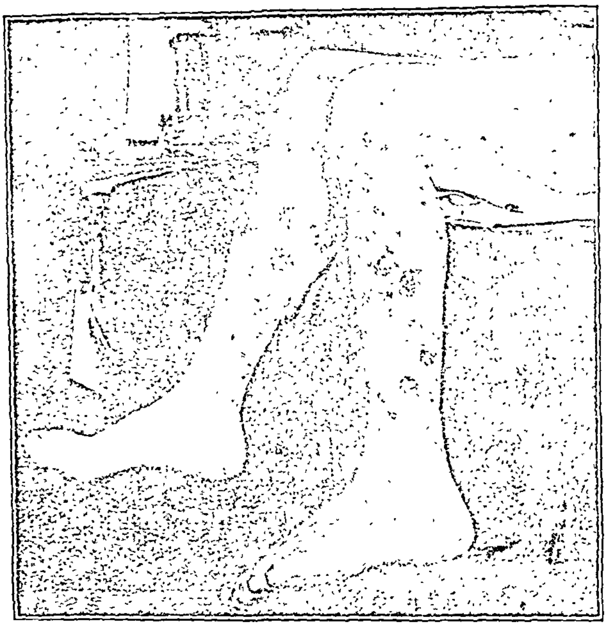

Fig. 10.—Severe secondary syphilis; papulopustular ulcerative syphilid of the legs (Case 5).

The syringe used (Figs. 4 and 5) is a Record with a twenty-one gauge needle as seen in the cut. The best place to give the injection is in the outer quadrant of each buttock, carrying the needle in at a slant of 45° from above downward as is shown in the illustration, to permit the solution to gradually separate the muscles. The patient should always be put on the abdomen or side for half an hour. This is the method employed in Lesser's clinic.

DOSE

According to the printed instructions which accompany the ampoule of salvarsan, the average dose intravenously is 0.3 gm. for women and 0.4 gm. for men. This is entirely too small and will surely be followed by recurrences, as has been proved by Alt and Schreiber,[2] Miekley[1] and others. One can safely give the full contents of the ampoule, 0.6 gm., to men, and 0.5 gm. to women unless they are otherwise affected by disease. And it is safe to follow this up after four or five days with an alkaline intramuscular solution of the same strength, or again in ten days with the same strength intravenously. I have repeatedly given the injection intravenously followed by an intramuscular injection in five days, and in numerous occasions I have repeated the intramuscular injection five weeks later, using 0.6 gm.

I have sent all of my patients to the hospital for their first injections, but being encouraged by the absence of symptoms I attempted with some patients to give the second injection in my office. This, however, I find is not at all satisfactory, for in some of these cases the shock which followed the injection was extreme, and the patients were not able to go home for some hours. I have repeatedly given the injections interscapularly into the muscles of the back and at the angle of the scapulæ into the latissimus dorsi muscles, but I cannot see the superiority of this location over the injection in the buttocks, except that it permits the patients to get around a little more easily. Some observers have used a local anesthetic following or preceding the injection, but as the pain is only transitory and of much less severity than that which occurs later, I cannot see that it has very much value. Dr. Marks[3] recommended 1 c.c. of 2 per cent. phenol, to be mixed and administered with the injection. I have administered a rectal suppository containing 1/4 grain of opium, which seems to act very well.

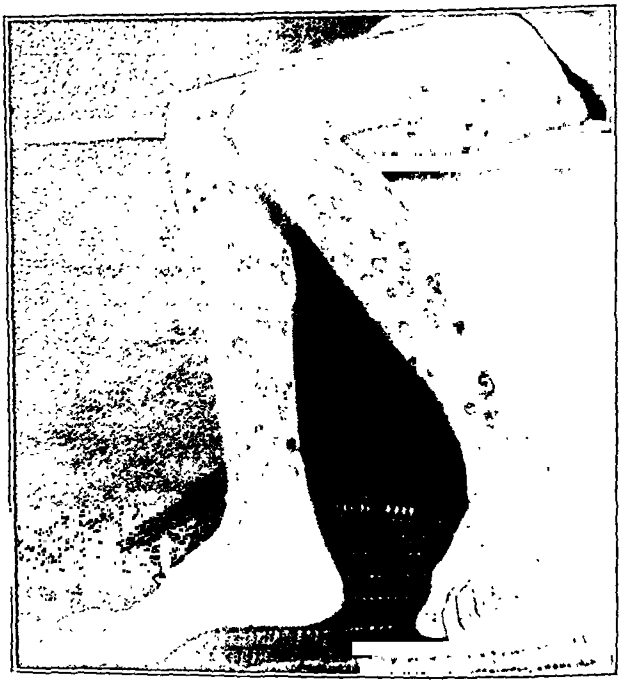

Fig. 11.—Only pigmentation and slight scaling left after thirteen days (Case 5).

At the present time it is best to treat all nursing children by a previous full-dose injection into the mother. If this cannot be done, the alkaline solution is injected into the buttocks, and the dose should be from 0.02 to 0.03 gm., depending on the age of the patient.

[3] Marks: Interstate Med. Jour., Jan. 1, 1911, p. 32.

MODE OF ACTION: INTRAVENOUS METHOD

If the solution is placed directly in the blood-stream, the specific acts immediately on any spirochetes that happen to be there and it depends on the larger or smaller number of organisms in transit through the lymphatic or blood-stream whether the symptoms which follow are more or less acute.

There is a period of quiescence following the injection for about five or six hours, then there occurs general malaise, followed by a chill, abdominal cramps and vomiting. The cramps and vomiting may be repeated and last several hours, the temperature rising sometimes to 102 or 102.5. As a rule by another six hours it is normal.

This is typical only of those cases in which the spirochetes are easily accessible. In one of my cases with an extensive papular eruption, there were only abdominal cramps and diarrhea. There is no question but that the intravenous method in proper hands is good, as it is followed by practically no unfavorable symptoms, but in order to obtain a maximum amount of effect it must be repeated again and again. The only danger lies in a puncture of the vein, with consequent paraphlebitis taking place.

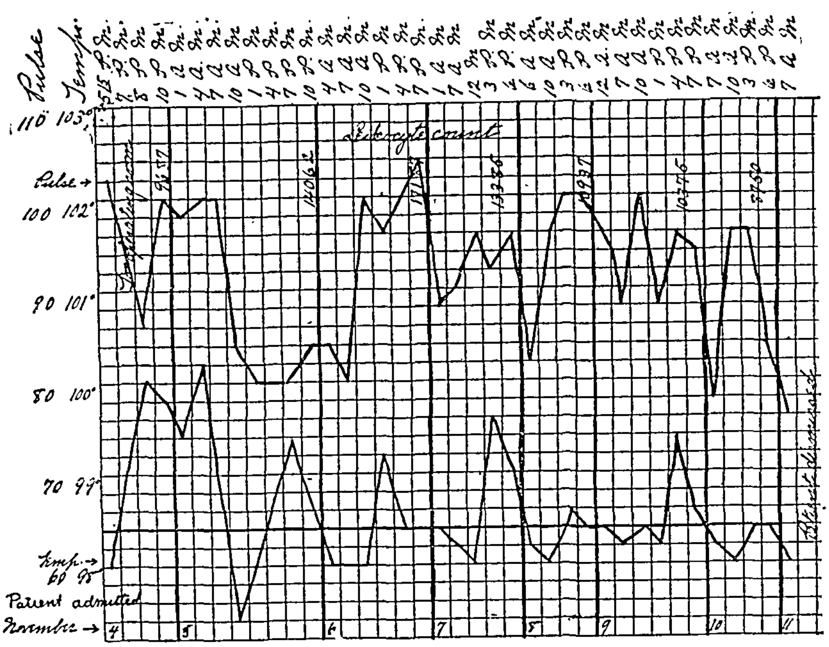

Fig. 12.—Chart showing pulse, temperature and leukocyte count in Case 5 (see Figures 10 and 11). The temperature and pulse ran a little higher here, but the leukocyte count went to 17,187. This patient has since had two injections, but fails to obtain a negative Wassermann reaction. He has since been put on mercury treatment.

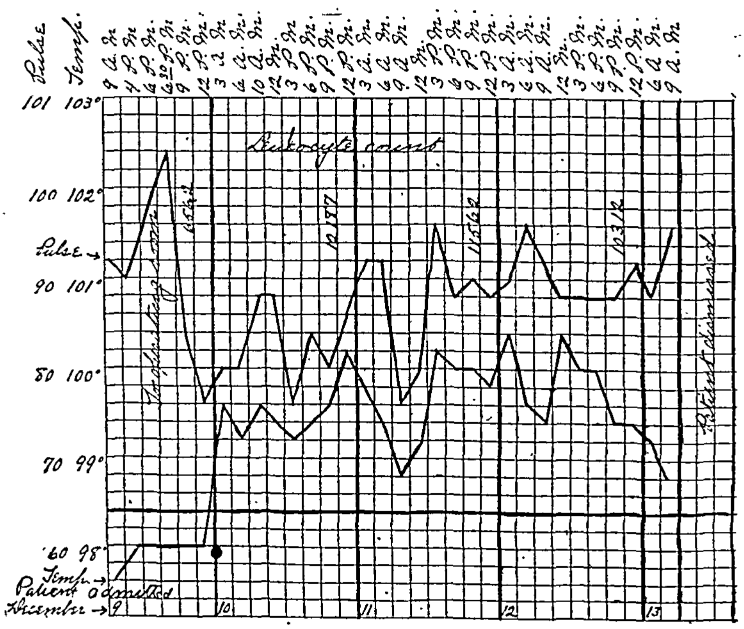

Fig. 13.—Chart showing pulse, temperature and leukocyte count of a case of Erb's spinal spastic paraplegia of syphilitic origin. This count is low, as was the case in all patients treated in whom the infection was of long duration and characterized by minimum destruction of tissue.

MODE OF ACTION: INTRAMUSCULAR METHOD

In order to avoid attacks of fainting and shock, which at times accompany the injection (I must say that this liability is greatly lessened with the newer salt, salvarsan) it is best to place the patient lying on the abdomen and always to disconnect the needle to see if there is any hemorrhage present. It has not been necessary except in a few instances to administer any opiate; and the more remote the infection, the less severe, correspondingly the reaction has been, so that in some of the tabetic patients who were treated, the local reaction was practically nil. Since I have been carrying my injection well to the outer margin of the buttocks, the ensuing neuritis has been practically absent. Frequently the pains are severe, radiating down to the foot, simulating a severe sciatica, but as a rule in several hours they pass off. When these injections were given into the muscles of the back, the referred pains in the abdomen, the arms and the hands were often very severe.

Over the site of the injection there comes an acute sensation of pain, which usually lasts about five to six hours. This is replaced by a dull sensation and a feeling of stiffness that rapidly changes to pain, reaching its maximum on the third to fifth day. Following the injection the area soon becomes boggy and red, resembling erysipelas in the severe infections, so that the patients are not able to sit down. This also does not, as a rule, reach its maximum effect until the third or fifth day.

Sweating.—This occurs in every case in which there is any systemic infection, but in none of my cases was it ever due to any extraneous organisms. It is caused by the endotoxins that are formed from the killed spirochetes. It usually begins the first night following the intramuscular injection and may continue for ten days. It usually reaches its maximum effect the third to fifth day and then gradually subsides. It is not present after the second injection in such a perceptible degree.

Using the neutral suspension, numerous cases of abscess have been reported. This is attributed either to the method of preparation, as in this way it is not easily kept sterile, or to the fact that the salt injected subcutaneously acts as a foreign body.

In none of my cases has there been the slightest sign of abscess, but unless the strictest asepsis is carried out, this surely will happen as a complication.

As a rule the swelling subsides rapidly and is fairly well absorbed at the end of the second week. Some nodules may remain unabsorbed for many weeks. This is particularly true after the more concentrated solutions. For a time I prepared my solution with a 20 per cent. solution of sodium hydroxid, dissolving the salt in 9 c.c. of water, so that when finished the whole dose was contained in 10 c.c. of solution. This in particular was followed by considerable pain and by nodules.

The personal element, however, plays an important rôle in regard to the effect of the injections. Women as a rule, bear them better than men.

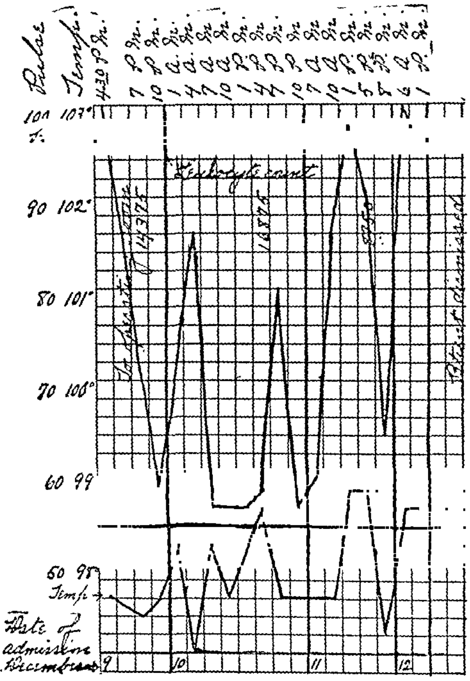

Fig. 14.—Chart showing pulse, temperature and leukocyte count in a case of latent syphilis complicating pulmonary tuberculosis. The count here is a little below average, but the local reaction was most severe. After five weeks his Wassermann reaction remains positive.

If the pain is severe, hot sitz-baths together with hot applications are of most benefit. The insomnia that follows after the injection, while at first due to the pain, is later the result of the stimulating effect of the arsenic. The general condition may remain undisturbed, though there may be loss of appetite, and malaise, but this passes off rapidly and in a week there is a wonderful stimulation (as Fritz Lesser[4] calls it, "the organotropic effect of the arsenic"). There is an increase in weight and general nutrition, including an improved blood-picture.

In a few cases there were numerous urticarial rashes after the second day. These, however, were transitory and caused practically no inconvenience.

The Herxheimer reaction was present numerous times (local irritation of spirochetal foci); but it was most marked in late secondary manifestations. In one instance, I excised a dactylitis syphilitica, believing that it contained pus, but it was nothing more than a local reaction.

Urine.—There have been no quantitative examinations made for arsenic. Albumin and casts have been found numerous times, but these were always transitory. A most careful examination of the urine was made of the patients who had received the second injection, and only in two instances were there any symptoms of renal irritation.

Temperature.—In the majority of cases the temperature was influenced but slightly, rarely going beyond one hundred degrees, often remaining perfectly normal; but occasionally there was a sharp rise, especially if the combined method had been used and the first injection had happened to kill a large number of spirochetes.

Pulse.—This varies with the degree of pain and the general condition. Of course, being a new form of treatment, the suspense and excitement often cause an unnatural rise.

Leukocyte Count.—In all cases a careful count was made from day to day and it can be safely said that there is a direct relationship between the relative number of killed spirochetes and the leukocyte count. In all cases in which the infection was recent and at all active, the leukocyte count was relatively high. In one case following an intravenous injection it went to twenty-eight thousand. Repeatedly, following the intramuscular injection, the count went from seventeen to nineteen thousand. On the other hand, in all cases in which the infection was at a minimum (this is especially true of tabetics) there was only a slight leukocytosis. As Neisser[5] has shown, there is no reaction in healthy non-syphilitic patients. We might, then, use this method in a measure to ascertain whether our treatment has been effective.

REPORT OF CASES

At the present writing I have treated sixty-two patients. I wish, however, to report on twenty-eight cases in detail, as the others have not been under observation for a sufficiently long time.

The medical examinations were made by Dr. Milton M. Portis and the ophthalmologic examinations were made by Dr. Cornelius A. Leenheer.

These cases include:

1. Primary syphilitic lesions after the Wassermann reaction was positive, but before there were any secondary skin manifestations.
2. Early secondary syphilitic lesions.
3. Late secondary syphilitic lesions.
4. Tertiary syphilitic lesions.
5. Syphilis of the nervous system.
6. Latent syphilis with only a positive Wassermann reaction.

Unfortunately, I was not able to observe a primary lesion sufficiently early to show only a negative reaction, and as a consequence I was not able to apply Ehrlich's theory of *therapia sterilisans magna* in an ideal case.

1. Primary syphilitic lesions after the Wassermann reaction was positive. In this series there are four cases.

Case 1.—The patient, J. F., 19, single, came under observation on Oct. 31, 1910. There had been an incubation period of fifteen days. The sore had been present three weeks at the time of examination. A few spirochetes were found. The Wassermann reaction was positive.

On Nov. 3, 1910, an injection of 0.5 gm. (10 c.c. of solution) was made into each buttock. The first picture (Fig. 6) was made Nov. 3, 1910. Complete healing took place in twelve days (Fig. 7). A Wassermann examination Nov. 28, 1910, was negative. On Dec. 12, 1910, a second injection was made, 0.6 gm.

---

[4] Lesser, Fritz: Berl. klin. Wchnschr., Oct. 24, 1910, p. 1975.

[5] Neisser: Berl. klin. Wchnschr., Aug. 8, 1910, p. 1485.

in concentrated alkaline solution. On Jan. 8, 1911, Wassermann still negative. On Nov. 28, 1910, I excised the remaining sclerosis at site of the primary lesion and this was examined for spirochetes by Dr. Maximilian Herzog after Levaditi's method. His report is as follows:

"Microscopic examination showed the mass removed to be composed mostly of granulation tissue which exhibits the characteristic endo-, meso- and periphlebitic vascular changes generally so well marked in primary and secondary syphilitic lesions. No spirochetes could be found in the silvered section, however."

It is needless to say that I realize that in due course of time the spirochetes would migrate from the lesion without any treatment whatever, but we had a considerable amount of granulation tissue left at the site of the primary lesion. The Wassermann reaction was negative and it was a question whether or not any organisms remained locked in the tissue, being so insignificant as not to produce a positive Wassermann.

Iversen[6] has followed out the same idea by examining the inguinal glands for spirochetes. He examined ten patients, three to five days after treatment and although the spirochetes had been present in great numbers before the injection, they were absent afterward.

In the above case there was a more perceptible reaction following the second injection, general malaise, chilly sensations and nausea. This, I felt, was due to an anaphylactic reaction, but in the light of similar conditions in other patients, I attributed it to the action on the spirochetes with resulting endotoxemia, the general condition of the patient being wonderfully good.

CASE 2.—The patient, M. E., was given a combined treatment, intravenous injection followed in five days by an intramuscular injection. After the intravenous injection he suffered a violent attack of chills, vomiting and abdominal pains, with a temperature of 102 F., which promptly receded the following morning. In three weeks he gave a negative Wassermann reaction, which four weeks later, on Jan. 8, 1911, was still negative.

I have used the intravenous method in the other cases of this series, in none of which was the reaction so acute. This I attribute to the solution catching a large number of spirochetes in the blood-stream, as the injection was given at the time that the first eruption should make its appearance. In the other patients so treated, the eruption had been out many days. The organisms were entrenched, so to speak, in the tissues, consequently the general reaction was not so acute and characterized only by cramps and diarrhea.

Two of the patients in this series have maintained a negative Wassermann reaction; the other two still show a positive reaction. All have had two injections, and no return of symptoms.

2. Early secondaries from one to six months' duration, characterized by skin eruptions and mouth lesions. This series comprises ten cases. The oldest case is of four months' duration, the shortest six weeks. All have had a second injection from the fourth to fifth week after the first, except one case, regardless of whether their Wassermann reactions were negative or positive. In none of these cases has there been any return of external signs of lues.

CASE 3.—The patient, B. B., 18, single, was infected April 1910; chancre on left tonsil. Secondaries appeared May 7, 1910. The diagnosis was secondary lues, only manifested by external lesion in throat.

The patient was put on rubbings which were continued until July 10, at which time there were no external signs of lues. He was put on proto-iodid pills, 1/6 gr. three times a day. In September plaques appeared on both tonsils. On Oct. 17, 1910, the day before treatment, examination for spirochetes showed twenty to thirty in the field. Next morning, October 18, an injection was given, 0.5 gm. of the alkaline solution, 10 c.c. in each buttock. The second day, no spirochetes were to be found; the fourth day, complete healing. Nov. 11, 1910, the Wassermann reaction was negative; likewise on Jan. 8, 1911. Jan. 15, 1911, the injection was repeated, 0.6 gm. The patient's condition was excellent.

CASE 4.—Figure 9 shows the handwriting of a patient with cerebrospinal syphilis that occurred during the secondary manifestations. The patient was infected six months previously and at the time of his cerebrospinal disturbance he had plaques on the tongue, a discrete papular eruption and condylomata. At the time of examination, Oct. 18, 1910, he was suffering from a right hemiplegia, and ptosis of the left eye, the left side of the mouth drooped, there was a slight delirium, incoherent speech, and slight comatose condition. Spirochetes were present in the plaques, and the Wassermann reaction was positive.

The patient was given 0.6 gm. in an alkaline solution into each buttock. The temperature never went higher than 101 1/5 F., the pulse never above 90. Three weeks after injection the man walked into my office in a greatly improved condition. While he could not tell me his home address, he was perfectly able to discuss the topics of the day.

The patient's general improvement has been most striking. He had another injection of 0.6 gm. at the end of the fifth week but the Wassermann reaction still remained positive. He has since gone back to work. Dr. Hugh T. Patrick saw this patient on two different occasions, the first time two days before the first injection and the second time eight weeks later. Dr. Patrick's comment was that the patient was "altogether a different man, but obviously not yet normal."

CASE 5.—J. M., aged 28, married, was infected July 12, 1910. The patient was dissipated and his condition poor. Rubbings with mercury, and potassium iodid internally were employed. This treatment was continued until the time of injection. The Wassermann reaction was positive.

Figures 10 and 11 illustrate an extensive papulopustular ulcerative syphilid that extended over the whole body, but was most marked on the legs. The pictures were taken fourteen days apart, the first on Nov. 13, 1910. The first injection was given Nov. 14, 1910, 0.6 gm. in alkaline solution, 10 c.c. into each buttock. The second picture was taken Nov. 26, 1910. The second injection was given Dec. 11, 1910. The second Wassermann reaction, Dec. 10, 1910, was only slightly positive; the third, Jan. 15, 1911, was again positive.

Five of these patients obtained a negative Wassermann reaction from the third to the fifth week after their first injection. All were injected a second time and have remained negative up to the present writing. The other five have never obtained a negative Wassermann but have been reinjected. There has been no return of symptoms.

3. Late secondaries after the sixth month.

In this series there are eight cases; all the patients have had their infection for six months to two years. All showed either external signs of lues or mouth or throat-lesions.

CASE 6.—The second patient in this series presented plaques on the tongue. These had been present with only slight remissions for one year. The patient was injected in the morning and by afternoon there was sharp bleeding in the lesions and by the second day a thin epithelial covering had begun to form. All healing was completed in one week; at the end of three weeks there was a negative Wassermann reaction; the fifth week a positive reaction. Two days later a second injection was given; this was followed the next day by general malaise, chills, nausea and vomiting; temperature 102° F. The following morning temperature normal.

At first I attributed this also to an anaphylactic reaction, but the incubation period was too short. It was further too late for an acute toxemia following the administration of the salvarsan. My deductions here are the following: The pathologic-anatomic lesions so securely held the spirochetes that the first injection only permitted the outer protecting wall to be influenced, while the second injection then was able to attack a large number of organisms, the patient suffering from an acute endotoxemia following the killing of so great a number. It is just this class of cases in which I believe the intravenous method to be of little value, as the remedy is eliminated before it has time to produce a maximum amount of effect.

---

[6] Iversen: Deutsch. med. Wchnschr., Oct. 13, 1910, p. 1899.

I have not been able to obtain a negative Wassermann reaction again in this patient, but there has been absolutely no sign of any recurrence. In order that I may not lose the advantage that I have gained over the disease, I have put him on mercury treatment until such a time as I deem it expedient to repeat my salvarsan.

Another patient in this series, in whom I was able one year ago to get a negative Wassermann reaction after rubbing into him 100 grams of mercury, had an ulcerative syphilid in the right nasal opening at the time of treatment and a dactylitis of the middle finger of the left hand.

These lesions showed a beautiful Herxheimer reaction; also the site of the old chancre was affected the same way, showing again that the organisms must be well anchored in the lesion, and emphasizing how little value one can place in a single negative Wassermann.

4. Tertiary syphilis, one case.

This case presented a gumma involving the septum. Healing was prompt, although the Wassermann has still remained positive; but there has been a wonderful nutritional change, the patient gaining twenty pounds.

5. Syphilis of the nervous system.

In this series there are three cases; two cases of tabes and one of Erb's spinal spastic paralysis of syphilitic origin. One of the tabetic patients reports an improvement of pain, but there has been no subsequent Wassermann test. The other tabetic patient after two months shows a negative Wassermann reaction, with a cessation of the pain of tabetic crisis. The patient with Erb's spinal spastic paralysis of syphilitic origin also shows improvement of the vesical and rectal sense and action, lessening of rigidity in the abdominal and leg muscles, disappearance of dragging of toes, increased freedom in movement of right ankle, and improved sensation in right leg, but increased patellar reflexes in both legs and increase of ankle-clonus on right side. The pulse, temperature, and leukocyte count in this case are given in Figure 13.

6. Latent syphilis, manifested only by a positive Wassermann test.

In this series there are two cases.

In the first case there has been no change in the Wassermann reaction after six weeks, but the nutritional change is well marked. The second case was complicated by tuberculosis of the lungs. Here there was also no change in the Wassermann reaction, but nutritional change was marked. The pulse, temperature and leukocyte count are given in Figure 14.

PROGNOSIS

From the many reports that have appeared the prognosis as to the efficiency of salvarsan is good. To believe that we have a twenty-four-hour cure for syphilis is indeed a mistake, but that we have the best means yet discovered to combat syphilis is true.

Unfortunately, salvarsan has a bad heritage and still more unfortunate is the fact that it is somewhat complicated in regard to administration and as a consequence the future will undoubtedly unfold many calamities following its misuse.

That the possibility of a *therapia sterilisans magna* is not a fruitless idea of Ehrlichs is conceded by all rational syphilographers, but for its successful culmination one must see the patient extremely early, make a diagnosis before there is systemic invasion (before the Wassermann is positive), effectually destroy the lesion and give the combined treatment (intravenously and intramuscularly) at the earliest possible moment.

Unfortunately, the syphilographer does not see the larger number of cases early, and for the successful carrying out of the ideal method he will have to depend on the family doctor in order to put these cases under treatment successfully.

The longer a patient has been infected with the *Spirochæta pallida*, the less chance is there for a speedy cure. In my cases, notwithstanding the fact that symptoms disappeared, the Wassermann remained positive in all that were infected longer than six months; and any physician who tells a patient that one injection is going to rid him of his syphilis forever is guilty of gross deception. To give a patient one injection and permit him to wait, is clothing him with a false security, as his symptoms will surely return unless some other form of treatment is added.

At the present writing I am re-treating all my patients in the fifth or sixth week. In those that have gained a negative Wassermann reaction before the second injection, I stop treatment after the second injection. In those that still show a positive Wassermann reaction, I continue the treatment with mercury until such a time as I feel justified in injecting the salvarsan a third time. By so doing, I am not only holding the advantage gained by the action of salvarsan, but am continuing the treatment to the best possible advantage.

Neisser[7] says that in the present enthusiasm over salvarsan we seem to forget that we were *ever able to* cure syphilis with mercury, and he suggests that we use mercury as an ally to salvarsan. Even Ehrlich[8] says that the best way to combat the disease is by different kinds of treatment, the same as a general would attack a hill "from all sides."

The biologic management of the patients after treatment with salvarsan is of the greatest importance if we wish to carry them to a successful termination. In fact, it is the only method available of controlling the disease before external manifestations occur.

A patient in whom the reaction persists after treatment must be considered as not cured. If the reaction disappears we have to differentiate between two possibilities: either we may have a true cure, which is indicated by the lasting disappearance of the reaction, or on the other hand, we may be dealing with a transitory negative phase, due to the fact that the remaining spirochetes are so diminished that those still left are not able to produce a reaction, and when they have again increased in number a positive reaction will again occur. This positive relapse without external manifestations is an indication for further treatment.

CONCLUSIONS

1. We have in Ehrlich's remedy a powerful agent against syphilis.

---

[7] Neisser: Deutsch. med. Wchnschr., Oct. 13, 1910, p. 1889.

[8] Ehrlich: Deutsch. med. Wchnschr., Oct. 13, 1910, p. 1893

2. A single injection has in favorable cases approximately the same result as four to five months' treatment with mercury and iodin.
3. It may show a brilliant effect in cases in which mercury and iodin have failed.
4. Salvarsan has advanced the treatment of syphilis in a decided manner, but on account of its strong arsenic content, repeated doses may have a disastrous effect on the human organism.
5. Every physician should master the technic before attempting to use it. Only in this way will the drug be safely guarded from many pitfalls.

In closing I wish to thank Dr. Joseph L. Boehm, of St. Louis, for his kind suggestions and Dr. D. N. Spaulding, Dr. John H. Fletcher, Dr. R. Dawes, Dr. D. Borges, Dr. H. H. Redfield, Dr. J. H. Nowlin, Dr. J. D. Bartlett, Dr. G. H. Stannard, and Dr. Nelson Percy for their kindness in referring a part of my material to me.

INTRAPERITONEAL SHORTENING OF THE ROUND LIGAMENTS FOR RETROVERSION OF THE UTERUS

THROUGH THE TEMPORARILY DILATED INGUINAL CANALS AND INTERNAL RINGS, WITH CLOSURE OF THE WOUNDS BY A CAREFUL HERNIA TECHNIC *

A. GOLDSPOHN, M.S, M.D.
Professor of Gynecology in the Post-Graduate Medical School, and Senior Surgeon and Gynecologist to the Evangelical Deaconess Hospital of Chicago
CHICAGO

Eleven years ago, at the Columbus session[1] of this Association, I took the initiative in this country in assailing the various fixation and artificial ligament operations for retroversion and flexion of the uterus in women who retain a capacity to conceive. At that time the results of such wrong and misdirected surgery already began to appear on the continent of Europe, and no great amount of erudition in *a priori* reasoning was required to foretell what the outcome of the same would be with us. A rationale on anatomic and physiologic grounds was then presented, showing a direct antagonism between the interests in the technic of such operations and the interests of the uterus in gestation and parturition; that either only futile or temporary results on the one hand or disasters on the other would result in a large proportion of cases. I was free to do this because it had been my good fortune to supplant the superficial, blind and incomplete simple Alexander operation in my practice, with a thoroughgoing intraperitoneal bi-inguinal procedure, which I had then performed over 100 times and of which I reported the remote results after an average period of two years in forty-seven cases, two months later, August, 1899, at the Amsterdam meeting[2] of the International Congress of Obstetricians and Gynecologists.

No other operation for retroversion of the uterus has been so carefully studied and so severely tested as to its ulterior results by so large a number of operators as has the Alexander operation. Most operators, especially the devotees to the fixation and artificial ligament procedures, have reported the status (often the subjective condition only) of their patients only up to the time when they left the hospital, or when they received an oral or written statement from them, or to the time of a childbirth, without regard to the position and condition of their pelvic organs after childbirth, or to the possible existence of some other concurrent affection. This is grossly insufficient and unworthy of notice by a scientific body or by a decent medical journal. Likewise it is not enough to depend on the patients' statements of their subjective conditions, but their objective anatomic status must also be obtained by a careful examination; and both the subjective and objective findings should be taken after an average interval of two years has elapsed.

Since pregnancy and childbirth are the chief functions of these organs and involve the most signal metamorphoses in them, these reproductive physiologic achievements must also be accepted as the normal standard by which to gage the merits and demerits of operations on these organs. My "double test of pregnancy" implies that the given procedure does not hinder pregnancy or induce complications for labor. This simple test of pregnancy will be readily passed by the multitude of procedures on the round ligaments, by the artificial ligament operations in most cases and the seroserous fixations in many cases, but the severer crucial or double requirement, that displacement of the uterus will not recur after one or more subsequent labors, has been proved to be met successfully only by some of the round-ligament operations, and by none of the artificial ligament or fixation procedures in an acceptable percentage of cases. According to all real evidence or proof, so far as recorded, only round-ligament operations, and of these only those that do not place dependence on the tapering and useless distal ends of these ligaments to do any holding, are able to pass these severe but normal requirements successfully in an acceptable percentage of cases. The plain reason for this is that the round ligaments are a part of the uterus, and as such undergo with it both evolution (not stretching), during gestation and involution after labor, which is not true of any fixation or artificial ligament that human ingenuity or conceit may devise. That fact excludes all such operations aside from (1) bi-inguinal (Alexander) operation, and (2) transplantation of round ligaments into the abdominal wall by some one of the numerous minor variations in technic, all of which are fundamentally correct in principle.

What is the record of the bi-inguinal operation? In my last summary of this subject before this Section, five years ago, I reported twenty-two cases of my own, each of which had passed the double test of pregnancy successfully, after previous intraperitoneal bi-inguinal shortening of round ligaments, with the Bassini hernia technic in closure of the wounds, and with these I reported a collection of 147 similar cases by twenty-five other operators, making in all 169 double test cases. Among these were only three failures, and these were for cause: namely, two cases of prolapse in which the undue elongation of sacrouterine ligaments contraindicated round-ligament shortening alone, and in the third case it was due to violent intrauterine manipulation and infection by a midwife. To this collection of 169 cases there now to be added 115 more such double-test cases by the following operators: 18 by Epstein,[3] 7 by Fuchs,[4]

26 by Tillmann,[5] 14 by J. W. Taylor,[6] 28 cases by Hannes (Kustner),[7] and 22 cases by Leese.[8] Some of these operators mention a recurrence rate of from 3 per cent. to 4.5 per cent., which probably applies also to the patients that bore children. If so, we have 284 cases examined after one or more childbirths, with an average recurrence of displacement of less than 4 per cent. With such a record the results of all other operations for this purpose—aside from the transplantation of round ligaments—are not to be compared.

The recurrences have become much less frequent with those operators who have discarded the old extraperitoneal method and have drawn the ligaments out more thoroughly after dissecting back the peritoneal investment in the properly opened canal and internal ring, and have noted the proper degree of advancement of the fundus through the same. Very many operators have followed my lead to that extent in this matter, but only a small number of them have followed me to the full extent of severing adhesions by introducing a finger or two through the dilated internal ring of each side, drawing the tube and ovary into or out of this opening and resecting or removing them, as may be indicated. The ovary and outer half of the tube are suspended from the broad ligament at a point just back of the internal inguinal ring and are often drawn out of that opening more easily than into a median ventral incision. In breaking up adhesions no decent operator makes anywhere in the abdomen the enormous incision that would be required, together with more or less evisceration, in order to see these adhesions down in the true pelvis. We all sever such adhesions by the sense of touch alone no matter by what route they are reached. This route should not be chosen for patients with immovably fixed uteri and adnexa with indurations, etc., because this would be dangerous and a waste of labor in such cases, for the patients do not become pregnant whatever the procedure used. Their tubes are too badly injured, and therefore they are well enough served by some simple fixation or duplication of round ligaments, by way of a median section.

The reasons commonly advanced against my intrapelvic work in my bi-inguinal celiotomy, via the dilated internal rings, are not at all the reasons why I have practically discarded this operation in recent years. I did it in over 200 cases, together with curettage and operations on the cervix, perineum or rectum *in most* of them, with a mortality of less than 1 per cent. I had twenty-two cases crucially tested by pregnancy and labor, without abnormality or a sign of a recurrence or of a hernia in any of them. My total recurrences of displacement were less than 1.5 per cent. without ever resorting to a pessary after operation. The reasons why I have practically discarded this operation are as follows: (1) violent appendicitis has occurred within a year or two in a number of cases in which I had the opportunity to remove the appendix, and did not do it because of sentimental reasons and because it seemed to be, and always to have been, normal; (2) according to several writers, and according to sensible *a priori* reasoning, cecostomy is preferable to appendicostomy when indicated for treatment of the colon, and (3) we find this wholly useless vestige, club-shaped or otherwise, disposed to make trouble in so large a proportion of cases, which in the past have been free of plain attacks of appendicitis. Therefore I am convinced as to my duty to remove this menace nearly always, especially when I open the abdomen for a relatively minor indication such as ordinary uterine displacements are. This cannot be done safely through the inguinal canal as a rule.

Furthermore, it is often desirable to palpate the gall-bladder, the pylorus or a kidney, in conjunction with an operation for pelvic disorders, or to resect a dilated linea alba. All these can be done if a median ventral incision is chosen and enlarged when necessary. By the same incision the uterine displacement can also be cured in a creditable manner by transplantation of round ligaments into the abdominal wall; therefore this only real competitor of the Alexander operation properly becomes its successor. But in recent years a compromising combination has been made between a median laparotomy and shortening of round ligaments in the inguinal canals after Alexander's method. Both of these acts are done by way of a straight or curved transverse suprapubic incision, which need not always be made through the aponeurosis of the recti muscles. This affords sufficient opportunity for the required median section and also access to the inguinal canals for the Alexander operation, under intra-abdominal control of the proper degree of shortening of each ligament. This in substance has been done by Peterson,[9] Rumpf and Palm,[10] Werth,[11] Kustner,[12] Littauer,[13] and Broese,[14] and promises to become a standard procedure. The Alexander operation, thoroughly performed, however, with its principles and monumental results, before mentioned, has led the way to such still more salient procedures. It can, therefore, well rest on its laurels if it is never performed again.

But to those operators, if any there be, who are still performing the original so-called extraperitoneal (?) Alexander operation, especially if without opening the inguinal canal, I would like to say with something louder than the human voice and words that they are not doing their duty by their patients; that their implied promises of best efforts and normal services held out to these patients are tinctured with fraud. This type of operation should certainly be banished, because, first, as I have repeatedly stated, the adhesions of the ovary and the outer end of the tube are much more frequent than of the uterus itself, because in their vicinity infection by way of the tubes comes first. Adhesions of these small structures are very difficult to discover and are often not suspected when the uterus is movable. They are formed on these adnexa in their descended location, to which they sank with the retroverted body of the uterus. When the latter is brought forward into anteversion the adnexa cannot follow, being fixed at a lower plane. The enforced tension on these structures entails discomfort to the patient, and the direction of this traction, being opposed to that of the extraperitoneally (often imperfectly), shortened round ligaments, endangers their integrity and tends to induce a return of displacement of the uterus. Such adhesions of adnexa, beside a free uterus, are severed with the greatest ease by a finger within the internal ring, which, fortunately, is just in front of the parts.

Secondly, the round ligament does not slide or pull out from the broad ligament enough, once in every four or five individual instances (according to careful observation on this point in fully 130 cases), without some scissor-clips on the front blade of the broad ligament, which is always drawn forward into the ring. The shortened ligament then remains, pulling forward from the broad ligament at a point distant from the uterus, and therefore with little or no good effect on the displaced fundus uteri. This condition is very easily discovered by pulling on the broad ligament while the index-finger of the other hand is placed against the uterus through the ring, and it is just as readily relieved.

Thirdly, in the not infrequent cases of retroversioflexion, with a heavy fundus, the center of gravity of the body of the uterus is often posterior to a line joining the points of origin of the round ligaments, while the posterior cervical supports are elongated. In this condition the round ligaments will have to be dissected out extensively from the broad ligaments, usually along with a generous strip of enveloping peritoneum, and they must be given a new course quite directly forward; otherwise traction on them from the inguinal canals is quite as likely to bring the cervix rather than the fundus forward.

That extraperitoneal (?) shortening of round ligaments is insufficient, is shown by the high percentage of recurrences of displacements, even in cases that have not been tested by pregnancy. Longyear,[15] including two cases in which he could not find both ligaments, had 12.5 per cent. failures. Hannes (Kuestner)[16] had three recurrences of displacement after nine operations performed extraperitoneally, while after sixty-two operations done with opening of the canal and peritoneum and more thorough elaboration of ligaments, the patients were found, two years later, to be without any recurrence of displacement.

CONCLUSIONS

1. The improved Alexander operation thoroughly performed has more good and approximately perfect results recorded to its credit than, so far, are recorded to the credit of all other operations combined that have been performed chiefly for retroversion of the uterus.

2. No Alexander operation should ever be performed without digital exploration within the pelvis through both internal rings, to prove that no adhesions remain, and to prompt and facilitate an adequate dissection of the round ligaments from the broad ligaments to give the former a sufficiently forward course to hold the fundus uteri forward effectively.

3. Prolapse of the uterus, or retroversion due chiefly to elongation of the sacro-uterine ligaments, should be treated by shortening these ligaments, when possible, or by attachment of the psoas parvus tendon or a portion of the psoas magnus muscle to the back of the cervix, in the manner suggested by Harris,[17] and never by shortening of round ligaments as the chief act.

4. Inasmuch as transplantation of round ligaments into the abdominal wall by some one of the numerous minor variations in technic, secures a creditable correction of retroversion in most cases by way of a median incision, which is also available for appendectomy, and various desirable explorations within the abdomen, this manner of operating has largely and properly superseded the general type of operating by way of the inguinal canals.

5. A plan of operation that is still more correct anatomically and surgically, has, in recent years, been carried out by at least seven operators with satisfaction. It consists in doing first, a sufficient median laparotomy and the required intraperitoneal work, and secondly, in shortening of round ligaments within the opened inguinal canals themselves, both by way of a transverse suprapubic incision, either straight or curved upward and extending through the aponeurosis of the recti muscles, as may be required.

2120 Cleveland Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. COFFEY,* BALDY, GILLIAM, SIMPSON, DUDLEY AND GOLDSPOHN, FORMING A SYMPOSIUM ON OPERATIONS FOR RETROFLEXION OF THE UTERUS

DR. E. E. MONTGOMERY, Philadelphia: It is with considerable hesitation that I speak when the inventors have presented their various operative procedures. I class myself as an adjuster rather than an inventor. The number of operations that have been introduced for correcting and maintaining the uterus in its proper position is evidence that none of these has been exactly what was necessary in all cases, and I would not come to-day to advocate any particular operation as an absolutely sure cure in every case that might present itself. I have lived long enough in the profession to have gone through the various procedures that have been devised from time to time for this purpose. I have, of course, practiced the operation of ventrosuspension and ventrofixation. I had the misfortune in performing this latter operation in one case to have a knuckle of intestine slip around the band of adhesion and the patient die as the result of the constriction of the intestine. This accident led me in doing the Gilliam operation to obliterate the space on either side in which the intestines might slip through. Later I utilized the procedure of Dr. Simpson with that of Dr. Gilliam by making an opening in the anterior leaflet of the broad ligament, threading the ends of the ligature which have been passed around the round ligament into the eye of a Deschamp's needle and have carried this through the broad ligament until it has penetrated the aponeurosis as suggested by Gilliam. I much prefer the Pfannenstiel incision, as it permits of greater exposure of the parts. This procedure also enables us to get directly down on the site of the round ligament. We are directly over it and it is under our control during the whole procedure.

The operation suggested by Dr. Baldy certainly does lift up the uterus and probably sustains it better than any operation done on the round ligaments. The objections are the very extensive traumatism on the posterior surface of the uterus and the fact that it pulls out the ligaments from the peritoneum, leaving an extensive raw surface on the posterior surface of the ligament to which adhesions of the intestine and rectum are likely to occur. I have had the opportunity to operate on one of the patients who had passed through the hands of Dr. Baldy and found that this condition existed, drawing back the uterus after an operation had been done. This modification makes a fibrous band of the musculature which is effectual in maintaining the uterus in a forward position. The uterosacral ligaments are much like the Arctic circle—an imaginary line. They have been completely obliterated by the conditions which have led to the sinking down of the uterus and are consequently of little effect. The procedure suggested by Coffey of utilizing the peritoneum, bringing about extensive adhesions of the peritoneum, serves a most efficient purpose. Here the uterus is held up by adhesions and consequently the cervix drawn backward and upward and in that way the displacement is overcome.

DR. J. B. MURPHY, Chicago: I address you in this discussion as fellow gynecologists, because it is all surgical, and all of the gynecologists are going to become general surgeons. In the question of retrodisplacement we have important problems. The position in which the uterus arrives at the physician's office is in one of the two, three or four degrees of displacement into which we usually subdivide them. Those who have lived through the pessary period and know the great relief that the patient receives when the uterus is held forward with a pessary, put in intelligently, know the relief that can be obtained from replacement, when you do not do additional damage to the patient by its improper insertion. I say that after a considerable clinical experience. In the attempt to relieve the displacement by many of the operations, and in some of the patients by all of the operations, the treatment leaves the patient worse than when it was begun. Just why this is true we do not know, but we know it occurs. Therefore, in deciding on the operation we must individualize as to anatomic conditions present, taking note of the degree of displacement, the construction of the patient's pelvis, and of the supports which we are able to appropriate for the retention of the uterus.

[17] Harris, M. L.: A New Operation for Prolapse of the Uterus, THE JOURNAL A. M. A., May 14, 1910, p. 1605

* Some of these articles appeared in THE JOURNAL last week.

In the relief of displacements by anterior fixation to the abdominal wall, which I was supposed to discuss, I must say this, that I made the ventral fixation for a number of years in the majority of operations. In a considerable percentage of cases the patients had three causes of complaint against me: (1) When the patient sneezed she had to seize her abdomen because of the pain caused by the traction; (2) when she jumped from a street car or carriage there was a sensation of tension or of pain; (3) finally, elongation took place and the uterus returned to the previous position. In the evolution of the displacement, whether it is immediate, following a severe injury or strain, or whether it is gradual, where do you find the uterus in the third degree? Down in Douglas' pouch with the intra-abdominal pressure on the anterior wall. Where are your round ligaments running? If you examine the patients, and particularly the thin ones, you will find in the superlative degree of displacement, if you are going to appropriate the round ligament to the support of the uterus without changing its attachment, that you have another element to contend with—the round ligament, normally situated high up and near the corner of the uterus, has worked down one and one-half inches to the line. So you have lost your leverage support from its position. The round ligament, I consider, is the balancing cord of the uterus. It carries none of its weight, simply balances it, and the weight is carried from below. The most natural thing in its restoration would be to put the weight where it was before; but the weight remains, except that it is resting on the floor of Douglas' pouch.

I use the round ligament for restoration in cases in which there is a comparative degree of displacement. Recurrence is more frequent than agreeable, but I believe there is less discomfort to the patient than with the fixation. In the superlative degree of displacement I have followed another line of treatment. In a case of procidentia if you will make an incision in the Pfannenstiel line down to the *rectus muscle*, then split the rectus muscle in a line parallel to its long axis; draw out the uterus and cut off the round and broad ligaments down to the cervico-corporeal junction, then split the uterus parallel to the long axis of the body down to the cervix, turn out the lateral flaps, remove the mucosa of the tube and uterus down to the cervix, then sew the uterus to the external surface of the sheath of the recti after uniting the peritoneum and the aponeurosis of the rectus up around the cervico-corporeal margin of the uterus, it will then hold the bladder and the rectum up as long as the patient lives.

Dr. H. J. Boldt, New York: We have traveled through a veritable jungle of surgical interventions for the cure of displacements of the uterus, particularly posterior displacement. We might believe—judging entirely from what has been said by all except the last speaker, Dr. Murphy, who paid attention to other than surgical intervention—that perhaps there is no other method than surgical intervention. Moreover, judging from the number of operations which have been reported, off and on, for displacement of the uterus, it would seem that every woman who has a retrodisplacement of the uterus must have been subjected to a surgical intervention for the relief of that displacement. We must bear in mind that so far as the symptoms are concerned, caused by a posterior displacement, they very seldom are caused, except from a mechanical interference with the functions of the pelvic organs. Symptoms are usually caused by complications. When symptoms occur from a mechanical cause we need not at once resort to the opening of the abdomen. In that class of cases I believe the great number of patients can be treated effectually by the use of a pessary, applied with common sense. There are a few isolated cases in which a pessary will not relieve such conditions. In cases in which the fundus of the uterus tips over the upper part of the pessary, and in that class of cases alone, we should consider the desirability of surgical intervention. I believe, notwithstanding what has been said, that the ideal operation is the Adams-Alexander operation, through the inguinal canal, provided that there is no downward displacement. The moment we have descensus the operation is absolutely worthless. So far as intraperitoneal operations are concerned, they are indicated only in the presence of complications with the adnexa, when we have an adherent retroflexion.

All the argument, all the speaking done here, will have no effect on any of the men who have devised operations. The matter is one of personal equation. I believe there are merits in all. There are so many roads that lead to Rome we may have the benefit of any. My personal experience has led me to believe that the operation devised by Dr. Gilliam is the most satisfactory.

Dr. J. H. Carstens, Detroit: It seems to me that Dr. Boldt has struck the keynote. When I was a young man I had a patient with retroversion. I had been graduated at a period when there was a great cry against pessaries. So, of course, I did not use a pessary—thought they were injurious—and I treated the woman on general principles. She evidently was a great sufferer. She ceased coming to my office and the next thing I heard was that she had gone to a woman physician who had examined her and said she had a retroflexed uterus. She put in a pessary and cured her. I have found since then, as Dr. Boldt has said, that there are cases in which pessaries are valuable; for instance, in those cases shortly after confinement in which the uterus is large and heavy. Other cases are those of young girls and sometimes of married women. It occurs to me that if there are adhesions and you have to open the cul-de-sac, you might as well open it anteriorly and find out what is necessary to do rather than to perform the Alexander operation. The patients who require only pessary treatment and who have simple retroversions that produce no symptoms I do not see. The kind of cases we see are complicated cases in which we must do exploratory abdominal section. In one case I may take out a tube and ovary. In many of these cases I sew the stump in the lower abdominal incision, and even in patients subsequently pregnant no trouble has been experienced. In some of these cases I do an operation such as Dr. Bandler does. Sometimes one is good; sometimes another.

Dr. C. W. Barrett, Chicago: Fellow surgeons—I say that because a great gynecologist is something of a special surgeon, and not because every surgeon is a great gynecologist—we have had a great feast showing what the round ligaments and the false ligaments can do in the correction of retrodisplacement. If I remember aright there was another great feast at which there appeared certain handwriting on the wall, which translated, I believe, meant, "Weighed in the balance and found wanting." That applies to a number of the operations spoken of here for retrodisplacement. The soundest principles have been laid down by Dr. Goldspohn. His is the operation of safety. Ventrosuspension and ventrofixation were formerly the excuses you could offer the patient for making a vivisection, for studying anatomy and living pathology, and they have had a wonderful place, but they are dead operations. The satisfaction that each person has felt in an operative procedure only shows how easily we are satisfied, and this is the chief thing in the way of progress. We must have the very best thing that can be offered, for the best is none too good. Whatever operation we choose must follow certain definite principles. It must be not complicated. It must be safe, immediately and remotely safe. It must allow inspection and correction of conditions in the abdomen. Next, it must use normal ligaments instead of false ligaments. Goldspohn has laid this down definitely. It must have the best part of a ligament instead of the poorest part, because there is a better and a poorer part of the round ligament. Next, it must use the natural ligaments and place them normally. It must not sew up the round ligaments and run them anywhere. I do not condemn Dr. Gilliam for proposing that, but it is an evil of ventrosuspension that it runs ligaments from the peritoneal space. An operation to stand the test must meet these requirements. Such an operation will stand the double test of pregnancy. I thought at one time that I had devised such an operation. I had full possession of that thought for two years. Then I had to share the matter with Charles Mayo. In another year I think I shall have no connection with it at all.

Dr. H. O. Marcy, Boston: Many years ago I thought I knew something of this operation. I had studied hernia with a great deal of care; therefore I thought I knew all about the Alexander operation. I welcomed it. I did it. I thought I knew my anatomy. I failed. I discredited it. To-day I take the position largely of Dr. Montgomery. We must be guided by the different factors. First of all, if we can restore a patient by a well adjusted pessary, it is *prima facie* evidence that operations from below may cure. When they fail it must be, I think, an operation from above. That operation, several men have said, must be laparotomy, and that gives you the inspection as Dr. Carstens has said and the knowledge of the various factors with which one must deal. Then, after doing all sorts of operations on the ligaments, in a general way, I have operated for quite a number of years—transplanting the round ligaments a little higher, making a new inguinal canal, reproduced to the normal pattern—for it is a congenital defect. The peritoneum must be so infolded that raw surfaces are not left within the abdominal cavity.

Dr. W. H. Wathen, Louisville: If once a surgeon begins to treat these patients all on the same principle he will never be successful. Each patient must be treated as an individual case and the existing pathologic conditions must be met. You hear a great deal said about shortening the round ligaments, the utero-sacral ligaments, and the various structures, to hold the uterus in position. It has never yet been demonstrated what does normally hold the uterus in place. We do know that there are structures above the perineal floor and there are structures below the uterus that participate in this, and whenever you find a defect in the structures you must treat such defect as encountered. I have performed nearly all the operations discussed to-day because in my line of work I have had a relatively large experience, and I have found less trouble and better results by anterior suspension. I have had no trouble following pregnancy. As Dr. Dudley has remarked, if in a case of retrodisplacement you perform any or all of the operations for the cure, yet do not repair the pelvic floor and suspend or elevate the bladder, you will never secure permanent success. If you make an anterior suspension in women not past the childbearing period by one suture only, and then build up the pelvic floor and bladder wall you will have success. If the woman is past the child-bearing period, then make a firm anterior fixation instead of a suspension, and if the uterus is too large amputate a large portion of the cervix, unite the vagina to the stump of the cervix and at the same time repair the pelvic floor, and, if needed, separate the anterior wall of the vagina from the bladder, elevate it by an approved method and then do a uterine suspension or fixation as indicated by the age condition of the patient.

I often perform the Gilliam operation, or some of its modifications, but I have never had any complication following anterior suspension of the uterus and I have performed the operation several hundred times.

Dr. G. Betton Massey, Philadelphia: I wish to emphasize the true cause of the displacement, which seems to have been overlooked by those who have spoken. The pathologic condition is not the displacement; it is the morbid condition of the uterus, the chronic inflammation of the uterus. Proof of that is found in the very large number of retroflexions that present no symptoms. This is shown also by the fact that many such patients in whom the diseased condition of the uterus has been cured, without complete rectification of the flexion, cease to have symptoms. With an experience of twenty odd years in the treatment of these cases of retroflexion I have never yet come across a single patient in whom the normal movable condition of the uterus needed to be destroyed by a fixation. I protest against all the operations described, and consider each and every one based on a misconception of the pathologic condition. It is now universally conceded that inflammation is due to germs and not to mechanical conditions.

Dr. George Gellhorn, St. Louis: The multiplicity of these operations forces me to the conclusion that none of them is ideal and applicable in all cases. But how is the gynecologist who has not had the originality to invent a method of his own, or who has not enough material to test all these methods, to choose the one he shall use in the individual case? Granted that all the claims made for the various methods are justified, namely, that they do not interfere with the functions of the genital organs, and that they are not any more dangerous than the disease itself, I think there are certain principles, the consideration of which will help us to limit the methods from which we may choose. In a case of retroflexion during the reproductive age I would avoid, first, any operation which fixes the uterus in an abnormal position. Examples of such are ventrofixation and ventrosuspension. Second, I would avoid any operation which deprives me of the sense of sight. There is no living man who is able to determine by bimanual examination in every case before the operation the absence of delicate adhesions or of minor pathologic complications about the tubes and ovaries, and if he does an operation of the Alexander or Goldspohn types, he deprives himself of the opportunity of freeing adhesions. Third, in an operation, as Dr. Barrett has pointed out, in which the round ligaments are used, I would try to use the better part of these ligaments. In some of these operations the weak part is still left to do the work of holding up the uterus. Fourth, I would avoid any operation which utilizes ligaments which have a very unimportant part in holding the uterus in place, and which are much too weak to do it. These are the objections to the Bovée type of operation, in which the utero-sacral ligaments are utilized. They are much too small to hold the uterus forward ordinarily, and if we find in a patient thickened and shortened utero-sacral ligaments we have to treat that condition because it produces distressing symptoms. In methods of this kind we produce artificially a condition which we are often called on to treat. The observation of these four principles will help us to limit our choice and I believe that of the numerous methods, only part of which have been mentioned here, there will be hardly more than two or three that will answer.

Dr. Henry T. Byford, Chicago: The strong end of the round ligament is in the inguinal canal. Those who have performed the Alexander operation, know that they have to cut some fascial attachments in the inguinal canal which give firmer support than the intraperitoneal muscular part, which is not a direct support; it is a balancer. If we want to suspend the uterus we had better eliminate the intraperitoneal, muscular portion, and depend on the other. This is what is done in the Baldy operation. In the majority of cases we do not want actually to suspend the uterus, we merely want a balancing action. Nature has experimented on woman for many years and knows how to hold up the uterus. Those operations which imitate Nature by making use of a new canal, or the old one, must be right in principle.

Dr. J. M. Baldy, Philadelphia: I feel a bit concerned that a general surgeon should speak of including us as surgeons. For a long time the gynecologists have been attempting to educate the general surgeons, but having so ignominiously failed I feel that probably we had better go to them and learn general surgery, as suggested by Dr. Murphy. The pessary was not discussed in my paper because I was not asked to discuss that subject. I see pessaries used in only two kinds of cases, and I can come to but one conclusion—that nobody in the East knows how to use them—for it has been said on the floor that there are good ways of employing them.

The two classes of patients who come to me with pessaries are those with perfectly normal anteriorly displaced uteri which need nothing, the patients having been made sick because some fool doctor has put a pessary in, and secondly, the patients with prolapse in which a pessary is of *no use*. Consequently I feel that nobody in the East knows how to use them, barring New York, and I intend to make a special trip to New York *to see whether they* are correctly used there. The ability seems to be confined to the West or to the Middle West, to Chicago principally. I showed by the model this morning how useless is the weak end of the round ligament in this operation. But I shall convince Dr. Gellhorn of his wrong position by *showing* him by the model that that end of the ligament is not used at all in the operation.

Dr. D. Tod Gilliam, Columbus, O.: The only criticism made of the operation which I have devised is that it leaves bands in the peritoneal cavity which are liable to produce obstruction of the bowels. "The proof of the pudding is the eating thereof." For ten long years or more this operation has been performed thousands of times by hundreds of different operators and there has never been a case of obstruction of the bowels.

Dr. F. F. Simpson, Pittsburg: I think we all recognize the fact that there are many displacements of the uterus that require no treatment and that many others are corrected by the pessary. There are many others in which some coincident disease, cardiac, renal, pulmonary, thyroid or other disease, *contraindicates any type of operation for any purpose. In such cases benefit is obtained from the use of the pessary.* The work of Drs. Reynolds, Goldthwaite and others has shown the importance of examination of the sacroiliac joint before the treatment of displacement by any method is to be considered. In reference to the employment of other operations than those devised by the individual operator, I have used and am constantly using parts of operations of different types and expect to continue to do so.

Dr. A. Goldspohn, Chicago: Dr. Coffey makes several assumptions that are *fundamentally wrong: (1) He assumes* that all abdominal as well as pelvic organs are held in their places chiefly by their peritoneal mesenteric supports. The truth is that the abdominal walls hold the abdominal organs chiefly, as we soon find out when these walls are defective. On the other hand, the uterine supports have either connective tissue or muscle in them in addition to the peritoneum. The free expansion of pelvic tumors shows that peritoneum holds not much better than skin. (2) That two layers of stomach or intestinal wall may unite and form one layer permanently, does not prove that the same will be *true of the broad and* round ligaments about the uterus, which are subject to the phenomenal and entirely peculiar changes incident to gestation and parturition, which does not apply to intestines, etc. In secondary laparotomies I have repeatedly seen all such plications and foldings of broad and round ligaments completely wiped out without leaving a trace of the former work, *after an intervening childbirth. In retroversion cases, the displacement had nearly always recurred.* That the proposed plications of broad ligaments proposed by Dr. Coffey do give way as above stated, is shown by his declaration that the involved round ligaments disentangle themselves later, and assume their usual course. This they could not do without the giving way of the broad ligament plications. The doctor practically constructs two connected links of a chain, and then claims that they become separated without either one of them being broken. The operations devised by Drs. Webster, Baldy, Ries and a number of others for retroversion, are inferior as to stability, because they depend on the tapering, *feeble outer* ends of the round ligaments to do holding, which they cannot do because of their feebleness and because of their course in areolar tissue extraperitoneally before entering the inguinal canals. I have practiced, for some years past, median section with removal of the appendix and other explorations, and have corrected *retroversions in a small number of cases by shortening the* sacro-uterine ligaments; in others by transplantation of the round ligaments into the abdominal walls, by several of the different methods, chiefly by a modified Gilliam operation, in which the uterus is drawn up more, so that it comes in contact with the abdominal wall, and the utero-vesical space becomes quite *effectively* shut off from the entrance of the small intestine. The *theoretical* arguments about intestinal strangulation, etc., do not apply to this form of the operation at least, of which I have over 500 that are fully two years old, and without any such disaster, or any difficulty in childbirth.

IMMUNOLOGY

A MEDICAL SCIENCE DEVELOPED THROUGH ANIMAL EXPERIMENTATION

FREDERICK P. GAY, M.D.
Professor of Pathology, University of California
BERKELEY, CAL.

Perhaps no other of the medical sciences can be so suitably discussed in relation to animal experimentation as immunology, because no other science has been so dependent on this method of attack for its development.

The science of immunity, or immunology, would explain the mechanism by which the animal body is enabled to resist disease. In addition to its fascination as a biologic science, immunology offers the added interest of the greatest human utility, the prevention and cure of disease; and precisely in this vital significance lies at once the importance of the science and a potential danger to its sound development. This danger arises in an overanxiousness to apply supposedly specific agents before the principles that underlie their apparent effect have been determined. The history of immunology has, indeed, brought into particular relief certain interesting relations of theory to practice, worthy of more philosophic discussion, but we may content ourselves with an attempt to point out the usual sequence of observed facts, logical deduction, inductive experiment, and, in *concluded chapters, application of principle* in the diagnosis and prevention of disease.

The relatively recent development of any exact knowledge of the mechanism of immunity is at first glance surprising, when we consider that certain examples of natural and of acquired resistance to disease have been recognized since ancient times. Some attempts to turn these recognized examples to practical use were from the beginning successful, but none of them was inaugurated with that understanding of the *principle involved* which brings the greatest utilitarian reward. It is obviously no lack of human interest in the subject which *has delayed* the evolution of immunology, but largely the lack of a suitable method of attack on so obscure a subject. The method was eventually furnished by the recrudescence of the experimental idea as *applied to* medicine and particularly as exemplified in the progress that has been made in determining the causation of disease. *Immunology*, indeed, parallels bacteriology both in chronology and in method. Before considering the development of the experimental science of immunity we may *outline*:

I. THE DATA OF IMMUNITY ACQUIRED FROM CASUISTICS

The first and most *wide-spread type of resistance to* disease is the inborn or natural immunity which is evident on the initial exposure to a given malady. With an increasing intensity, as expressed in more and more marked resistance to infection, natural immunity serves to differentiate individuals of a given race, races of a given species, and species of animals from one another.

---

* This paper is one of the series prepared for and reprinted by the Council on Defense of Medical Research of the American Medical Association for circulation among the public. Seventeen of these pamphlets are now ready, taking up the relations of animal experimentation to ethics, diagnosis, cancer, vaccination, the live stock industry, tuberculosis, typhoid, dysentery, plague, rabies, surgery, internal secretions, circulation of the blood, tropical diseases, etc.

The individual type of natural immunity may be noted whenever a group is subjected to equal chances of infection or contagion; certain individuals succumb while others resist. A familiar example to illustrate this relative individual resistance is given in any group of pathologists who are performing numerous post-mortem examinations; some members of this group are veritable martyrs to post-mortem infections, whereas others are practically immune. This type of resistance is frequently temporary and in all respects relative; it is dependent on certain subtle differences in general health and nutrition and may be evidenced by certain changes in the bactericidal properties of the blood, to which reference will later be made.

Natural racial immunity, to which attention was called as early as the sixteenth century, is in all probability dependent on differences in food and general hygiene. It is difficult to be certain in many so-called examples of racial immunity that have been given whether the increased resistance is in reality inborn or simply acquired through recovery from disease. The marked resistance of certain races of mice to a transmissible tumor (Haaland),[1] which resistance may actually be lowered by a change in environment, would seem a certain example of a natural racial immunity.

Species immunity is the most evident and distinctive type of natural immunity. The difference in resistance between any two species of animals to a given infection varies in general with the distance apart that these species lie in the animal scale. Although familiar examples of species immunity occur throughout the animal kingdom, those of the greatest interest occur in relation to a whole series of typical human diseases, syphilis, measles, typhoid fever, gonorrhea and the like, which never occur spontaneously in the lower animals, and cannot be transmitted to them or at best in modified form only. Recent studies with the higher anthropoid apes, however, have shown that at least certain of these typically human diseases (*e. g.*, syphilis and typhoid fever) may be produced in these animals because they are most nearly related to the human species. In a general way, species resistance may be attributed to differences in metabolism, body temperature, intestinal enzymes and the like.

Of far greater significance and practical bearing are those instances of immunity acquired through recovery from a given disease. It is a matter of human experience that man has usually but a single attack of many of the diseases to which he is peculiarly susceptible, such as smallpox, typhoid fever, measles and yellow fever. In the face of epidemics where only those that have been previously affected are spared it is evident that such recovered individuals are protected, not as the result of chance, but owing to some induced mechanism of protection against the disease. Similar conditions of acquired immunity have frequently been noted in domestic animals.

Logical deduction from these observed instances of acquired immunity long since led to attempts to reproduce this advantageous condition artificially. Empirical efforts have been made even among primitive peoples to induce in individuals some endurable form of a fatal disease so that they might subsequently be better protected from chance infection. The African Vatuas[2] have been reported as practicing an efficient form of self-immunization against snake venom; the Moors early protected their cattle from pleuropneumonia by running under their skin a knife that had been plunged into the lung of an animal that had died of the disease. It is well known that the Chinese and other peoples of the East protected themselves from smallpox by variolization, which was effected by inserting the scabs of human smallpox lesions in the nose of healthy individuals. A similar method was introduced into England by Lady Mary Wortley Montague in 1721 and was employed until the observations of Jenner on the relation of cowpox to smallpox in 1798 led to the present method of prevention of the disease by vaccination. The chance that a disease of cattle (vaccinia) is intimately related to a fatal human disease and that an attack of the one in the form of a localized disease would protect against the more generalized malady, alone rendered Jenner's observation fruitful. No generalized conception of the principle of "vaccination with a virus of diminished virulence," as later established by Pasteur, however, existed. This is evidenced by disastrous attempts that were later made to prevent measles, diphtheria and scarlatina by similar methods.

II. THE DEVELOPMENT OF IMMUNOLOGY THROUGH ANIMAL EXPERIMENTATION

Centuries of careful observation of facts obtruded by Nature in the course of devastating epidemics had taught at least two important principles in regard to resistance to disease: an acquired immunity follows recovery from an attack in perhaps the majority of acute diseases; and in at least one instance (smallpox) this acquired immunity may be artificially induced through a mild form of the disease. In the past thirty years the assets of utility from our knowledge of immunity have been multiplied to an extent that it would be difficult to estimate, to say nothing of the additional data of present theoretical interest which may ultimately be available in practice. And this advance has been rendered possible by animal experimentation.

It is the purpose of an experimental science to replace accident by design. A disease produced experimentally in animals offers innumerable advantages to one interested in its natural history; it offers the only method of obtaining the significant stages of the disease in complete series for more minute examination. Only the interruption of an experimentally produced disease at successive periods in its course can afford exact information as to the method by which infection spreads and immunity is produced.

The discovery of the fundamental principles of bacteriology by Pasteur and Koch, the isolation and cultivation of bacteria in pure culture, and the proved etiologic relation of a definite micro-organism to a given disease, gave new impetus to the principle of vaccination exploited by Jenner. The work of Pasteur and his pupils with the bacillus of chicken cholera on animals laid the foundation for the discovery of the great principle of vaccination by means of bacterial cultures of diminished virulence. This diminution of virulence was obtained, in the case of chicken cholera, by long growth on artificial culture media, and later, in the case of anthrax by subjecting the cultures to growth at high temperatures. Similar methods of vaccination have been employed in the case of swine erysipelas and blackleg. In all instances the method has been arrived at by careful experimentation on animals and the products now used broadcast in actual prevention are first tested for virulence on laboratory animals. It is not my purpose to enter into a discussion of the practical results of protective inoculation but simply to indicate how the method of animal experimentation in bacteriology enriched the data of immunity.

[2] Metchnikoff: L'Immunité dans les maladies infectieuses, Masson et Cie, Paris.

Immunology may be regarded as having been differentiated into a specialized science from the moment that effective attempts to explain the physiologic mechanism that protects immunized animals were made. Theories of immunity were offered by Pasteur, Koch and others, but they were based largely on speculation drawn from the bare results of infection rather than from experiments designed to expose the process of immunity itself. In 1876 Koch[3] attributed conditions of immunity to some change in the condition of the blood. Pasteur's exhaustion theory (1880)[4] supposed that bacteria fail to grow in immunized animals owing to a lack of proper nutritive substances. A similar condition could be produced in artificial culture media as was shown by the failure of fresh chicken cholera bacilli to grow in filtered media that had already served for the growth of this bacterium; the addition of a little fresh bouillon containing fresh nutritive substances permitted growth to proceed. Chauveau[5] in the same year would have explained immunity as due to the retention in the body of certain substances which inhibit bacterial growth. It is of interest to note that in none of these theories is any allowance made for active participation on the part of the animal itself in the production of resistance. The theories of Nägeli, of Buchner and of Grawitz do at least emphasize a reaction on the part of the animal itself, although they have proved in other ways inadequate.

It remained for Metchnikoff, a biologist, to give the first experimental evidence explanatory of the process of immunity. In 1882 Metchnikoff began recording his observations on the function of the white blood corpuscles in protecting the body from disease, observations which in his hands and in those of his followers have continued fruitful to the present day. Before Metchnikoff, mention has already been made of the presence and of the disintegration of bacteria within leukocytes and Panum[6] in 1874 had even suggested that such cells might be serving some protective purpose. The general conception of the accumulation of leukocytes which characterizes inflammation, however, was that it was a means of spreading rather than of checking infection. Metchnikoff had been making studies of the origin of digestive functions in cells of mesodermal origin. He suggested that the inclusion of particles and cells within leukocytes was due to an active digestive function in these mesodermal cells and ventured the assertion that their diapedesis during inflammation was a protective mechanism. In one of the crustaceans, *Daphnia*, which frequently suffers from an infection with a form of blastomyces (*Monosporon bicuspidata*), Metchnikoff was able to show that the outcome of the infection depends entirely on the completeness with which the blastomyces is engulfed by the leukocytes of the host. He was soon after able to demonstrate that frogs and mammals also combat experimental bacterial infection by a similar process of phagocytosis.[7]

NATURAL IMMUNITY FROM BACTERIA

Although this phagocytic theory of immunity at first encountered extreme opposition, its opponents have gradually yielded more and more toward complete acceptance of the interpretation that Metchnikoff has with persistence yet remarkable fairness of judgment insisted on. It is generally admitted that many forms of natural immunity in particular are best explained on a simple phagocytic basis. The more complicated types of acquired immunity are less directly, though unmistakably, related with activity on the part of the white blood-cells. Leaving until later a discussion of the part played in each form of immunity by the cells, we may briefly outline the mechanism of phagocytosis in those instances in which it has been shown to be distinctive.

In the first place, the phagocytic cells may be divided into two general types as regards function. The small, actively motile polymorphonuclear cells of the circulating blood are practically concerned only in making way with the bacteria which produce acute infections; these cells are called "microphages." Under "macrophages" are grouped the large mononuclear leukocytes and certain endothelial and fixed tissue cells; the function of these cells is to take up other animal cells, such as red blood-corpuscles and protozoa, and also certain bacteria, like the tubercle and leprosy bacillus, which produce chronic infections.

It has been shown by careful studies, both within the animal body and in mixtures made in the test-tube, that the phenomenon of phagocytosis may be divided into three phases. In the first phase the leukocytes approach non-virulent bacteria owing to a positive chemotactic influence which the latter exert. If the bacteria are markedly virulent, on the other hand, they exert a negative chemotactic influence. These important facts of positive and negative chemotaxis were ingeniously demonstrated by Bordet,[8] who placed small capillary glass tubes filled with the bacteria to be tested in the peritoneal cavity of guinea-pigs and later measured the length of the columns of leukocytes that had penetrated the tubes. After reaching the bacteria the phagocytes engulf them, owing in all probability to an active ameboid process, although it has been suggested that this apparent activity is due in reality to a simple physical change of surface tension. The bacteria, once within the leukocytes, are broken up by a process of digestion. An extract of leukocytes may be made which contains an enzyme (cytase) capable of producing this digestion at body temperature outside the body and the extract has been shown to vary in accordance with whether it is derived from microphages or macrophages. The extract of microphages (microcytase) is particularly active against bacteria and is effective only in an alkaline medium; it has little effect on animal cells. Macrocytase, on the other hand, derived from the mononuclear cells, works best in an acid medium and destroys animal cells.

The active opposition with which Metchnikoff's cellular theory of immunity was at first met was directly productive of important facts which at first seemed to attribute the active protective power of the blood to the fluid portion rather than to the leukocytes. In 1885 Fodor[9] showed that anthrax bacilli, when mixed with fresh rabbit blood in the process of clotting, were destroyed; and two years later Nuttall[10] showed that fresh defibrinated blood would produce the same effect. In 1891 Buchner[11] proved this bactericidal effect of fresh blood to be due to the cell-free blood serum, whether it is obtained by defibrination or by clotting. Buchner further described certain ferment-like substances in the serum to which this destructive power over bacteria is due and to which he gave the name of alexins (from ἀλέξειν to ward off or protect). The alexins resist freezing and thawing, but are destroyed by heating to 55 C. for one-half hour. They are unaffected by dilution in physiologic salt solution and may be precipitated with sodium sulphate. Such physical and chemical characteristics have caused alexins to be classed with the enzymes without any very profound knowledge as to their chemical composition.

Further studies, particularly those dealing with the origin of alexin, seem to have shown that the bactericidal property of cell-free serum is in reality no disproof of the correctness of Metchnikoff's conception of the cellular nature of natural immunity. There is good experimental evidence for the belief that the alexin of Buchner is never present in the blood plasma in the body, but is artificially liberated in blood serum by clotting, owing to a disintegration of the leukocytes which normally contain it. In other words, the "alexin" is synonymous with Metchnikoff's leukocytic ferment, the "cytase," which under usual conditions destroys bacteria within the cell (phagocytosis) and under abnormal conditions in shed blood is liberated in the serum. Many experimental observations have been adduced to prove this point. For instance it may be shown that the alexin varies with the degree of leucocytosis; leukocytic extract is essentially the same in its action as alexin; and alexin increases in the serum under conditions which favor disintegrating of leukocytes.

It would seem, then, that the leukocytes are largely responsible, either directly through phagocytosis or indirectly through liberation of cytase or alexin, for the condition of natural immunity from bacteria and animal cells. As we shall presently see, the study of conditions of acquired immunity, although in a measure complicating this explanation, has led to far greater insight of practical significance in combating disease.

IMMUNITY FROM TOXINS

At this point it is advisable both for reasons of chronology and exposition to interrupt temporarily our consideration of the mechanism of animal defense against bacteria as such. Bacteria that have gained entrance to the body are harmful, not only because they increase rapidly in numbers when unrestricted, but because they eliminate harmful products. These harmful products may be either simple chemical substances like acids and alkalies, bacterial proteins, known as ptomains, or more particularly, in certain instances, true bacterial toxins. Toxins are albuminoid substances, of unknown chemical constitution, which are specific both in their origin and in the effect they produce. They are endowed with certain other recognizable characteristics; they produce their harmful and specific effects only after a period of incubation; they are readily destroyed by heat; they act in very small doses; and lastly, as we shall presently see, they produce antitoxins. Pasteur, as early as 1880, noted that old bouillon cultures of the *Bacillus avisepticus* which had been filtered free from bacteria would, on injection into animals, produce symptoms of narcosis. In 1888 Roux and Yersin[12] described a toxin found in filtered cultures of the diphtheria bacillus which was fatal for guinea-pigs in very small doses. Although the possibility of specific protection from bacterial invasion by means of previous treatment with killed or modified bacterial cultures was then known, attempts at a similar protection against this diphtheria toxin were at first unsuccessful. In the following year Kitasato succeeded in obtaining a pure culture of the tetanus bacillus and in 1890 von Behring and Kitasato[13] obtained tetanus toxin from such cultures. They found furthermore that by treatment with certain chemical substances the toxins of diphtheria and of tetanus could be weakened so as to be better supported by laboratory animals; animals treated with these weakened toxins became immune from doses of the whole toxin that were fatal to the normal animal. And, more important still, it was shown that the blood of such actively immunized animals would protect normal animals against subsequent injection of fatal doses of toxin, or would even cure, within reasonable time limits, animals that had already received the toxin. These experiments form the rational basis for the present highly effective antitoxin treatment of diphtheria and for the prevention of tetanus.

The interesting studies of Ehrlich[14] as to the mode of interaction of antitoxin with toxin not only gave rise to an enormously ingenious and fruitful theory of immunity but determined the recognized method of estimating and standardizing, by the use of guinea-pigs, the exact curative value of diphtheria antitoxin. We need not concern ourselves with the theories of antitoxin effect, as their interest, although of ultimate utilitarian value, is immediately largely academic. In addition to the better studied toxins of diphtheria and tetanus, true toxins have been described as formed by cholera vibrios, the bacillus of meat poisoning (*B. botulinus*), the dysentery bacillus of Shiga and the *Bacillus typhosus*. The exact relation of each of these latter toxins to pathogenesis of the disease in question is not fully determined nor can any final word be given as to the efficacy of an antitoxin treatment in many of these instances. In the case of the dysentery bacillus, at least, almost certain results may ultimately be expected from specific antitoxin therapy.

ACQUIRED IMMUNITY FROM BACTERIA

Reference has already been made to the important discovery of Pasteur that animals could be immunized by means of cultures of diminished virulence. In 1886 Salmon and Smith[17] showed that pigeons could be immunized against the hog cholera bacillus by means of cultures that had actually been killed by heat. In 1888 Richet and Hericourt[18] proved that this antibacterial type of immunity is transferable from one animal species to another. Von Behring and Nissen[19] demon-temperatures. Similar methods of vaccination have been employed in the case of swine erysipelas and blackleg. In all instances the method has been arrived at by careful experimentation on animals and the products now used broadcast in actual prevention are first tested for virulence on laboratory animals. It is not my purpose to enter into a discussion of the practical results of protective inoculation but simply to indicate how the method of animal experimentation in bacteriology enriched the data of immunity.

Immunology may be regarded as having been differentiated into a specialized science from the moment that effective attempts to explain the physiologic mechanism that protects immunized animals were made. Theories of immunity were offered by Pasteur, Koch and others, but they were based largely on speculation drawn from the bare results of infection rather than from experiments designed to expose the process of immunity itself. In 1876 Koch[3] attributed conditions of immunity to some change in the condition of the blood. Pasteur's exhaustion theory (1880)[4] supposed that bacteria fail to grow in immunized animals owing to a lack of proper nutritive substances. A similar condition could be produced in artificial culture media as was shown by the failure of fresh chicken cholera bacilli to grow in filtered media that had already served for the growth of this bacterium; the addition of a little fresh bouillon containing fresh nutritive substances permitted growth to proceed. Chauveau[5] in the same year would have explained immunity as due to the retention in the body of certain substances which inhibit bacterial growth. It is of interest to note that in none of these theories is any allowance made for active participation on the part of the animal itself in the production of resistance. The theories of Nägeli, of Buchner and of Grawitz do at least emphasize a reaction on the part of the animal itself, although they have proved in other ways inadequate.

It remained for Metchnikoff, a biologist, to give the first experimental evidence explanatory of the process of immunity. In 1882 Metchnikoff began recording his observations on the function of the white blood corpuscles in protecting the body from disease, observations which in his hands and in those of his followers have continued fruitful to the present day. Before Metchnikoff, mention has already been made of the presence and of the disintegration of bacteria within leukocytes and Panum[6] in 1874 had even suggested that such cells might be serving some protective purpose. The general conception of the accumulation of leukocytes which characterizes inflammation, however, was that it was a means of spreading rather than of checking infection. Metchnikoff had been making studies of the origin of digestive functions in cells of mesodermal origin. He suggested that the inclusion of particles and cells within leukocytes was due to an active digestive function in these mesodermal cells and ventured the assertion that their diapedesis during inflammation was a protective mechanism. In one of the crustaceans, *Daphnia*, which frequently suffers from an infection with a form of blastomyces (*Monosporon bicuspidata*), Metchnikoff was able to show that the outcome of the infection depends entirely on the completeness with which the blastomyces is engulfed by the leukocytes of the host. He was soon after able to demonstrate that frogs and mammals also combat experimental bacterial infection by a similar process of phagocytosis.[7]

NATURAL IMMUNITY FROM BACTERIA

Although this phagocytic theory of immunity at first encountered extreme opposition, its opponents have gradually yielded more and more toward complete acceptance of the interpretation that Metchnikoff has with persistence yet remarkable fairness of judgment insisted on. It is generally admitted that many forms of natural immunity in particular are best explained on a simple phagocytic basis. The more complicated types of acquired immunity are less directly, though unmistakably, related with activity on the part of the white blood-cells. Leaving until later a discussion of the part played in each form of immunity by the cells, we may briefly outline the mechanism of phagocytosis in those instances in which it has been shown to be distinctive.

In the first place, the phagocytic cells may be divided into two general types as regards function. The small, actively motile polymorphonuclear cells of the circulating blood are practically concerned only in making way with the bacteria which produce acute *infections*; these cells are called "microphages." Under "macrophages" are grouped the large mononuclear leukocytes and certain endothelial and fixed tissue cells; the function of these cells is to take up other animal cells, such as red blood-corpuscles and protozoa, and also certain bacteria, like the tubercle and leprosy bacillus, which produce chronic infections.

It has been shown by careful studies, both within the animal body and in mixtures made in the test-tube, that the phenomenon of phagocytosis may be divided into three phases. In the first phase the leukocytes approach non-virulent bacteria owing to a positive chemotactic influence which the latter exert. If the bacteria are markedly virulent, on the other hand, they exert a negative chemotactic influence. These important facts of positive and negative chemotaxis were ingeniously demonstrated by Bordet,[8] who placed small capillary glass tubes filled with the bacteria to be tested in the peritoneal cavity of guinea-pigs and later measured the length of the columns of leukocytes that had penetrated the tubes. After reaching the bacteria the phagocytes engulf them, owing in all probability to an active ameboid process, although it has been suggested that this apparent activity is due in reality to a simple physical change of surface tension. The bacteria, once within the leukocytes, are broken up by a process of digestion. An extract of leukocytes may be made which contains an enzyme (cytase) capable of producing this digestion at body temperature outside the body and the extract has been shown to vary in accordance with whether it is derived from microphages or macrophages. The extract of microphages (microcytase) is particularly active against bacteria and is effective only in an alkaline medium; it has little effect on animal cells. Macrocytase, on the other hand, derived from the mononuclear cells, works best in an acid medium and destroys animal cells.

The active opposition with which Metchnikoff's cellular theory of immunity was at first met was directly productive of important facts which at first seemed to attribute the active protective power of the blood to the fluid portion rather than to the leukocytes. In 1885 Fodor[9] showed that anthrax bacilli, when mixed with fresh rabbit blood in the process of clotting, were destroyed; and two years later Nuttall[10] showed that fresh defibrinated blood would produce the same effect. In 1891 Buchner[11] proved this bactericidal effect of fresh blood to be due to the cell-free blood serum, whether it is obtained by defibrination or by clotting. Buchner further described certain ferment-like substances in the serum to which this destructive power over bacteria is due and to which he gave the name of alexins (from ἀλέξειν to ward off or protect). The alexins resist freezing and thawing, but are destroyed by heating to 55 C. for one-half hour. They are unaffected by dilution in physiologic salt solution and may be precipitated with sodium sulphate. Such physical and chemical characteristics have caused alexins to be classed with the enzymes without any very profound knowledge as to their chemical composition.

Further studies, particularly those dealing with the origin of alexin, seem to have shown that the bactericidal property of cell-free serum is in reality no disproof of the correctness of Metchnikoff's conception of the cellular nature of natural immunity. There is good experimental evidence for the belief that the alexin of Buchner is never present in the blood plasma in the body, but is artificially liberated in blood serum by clotting, owing to a disintegration of the leukocytes which normally contain it. In other words, the "alexin" is synonymous with Metchnikoff's leukocytic ferment, the "cytase," which under usual conditions destroys bacteria within the cell (phagocytosis) and under abnormal conditions in shed blood is liberated in the serum. Many experimental observations have been adduced to prove this point. For instance it may be shown that the alexin varies with the degree of leucocytosis; leukocytic extract is essentially the same in its action as alexin; and alexin increases in the serum under conditions which favor disintegrating of leukocytes.

It would seem, then, that the leukocytes are largely responsible, either directly through phagocytosis or indirectly through liberation of cytase or alexin, for the condition of natural immunity from bacteria and animal cells. As we shall presently see, the study of conditions of acquired immunity, although in a measure complicating this explanation, has led to far greater insight of practical significance in combating disease.

IMMUNITY FROM TOXINS

At this point it is advisable both for reasons of chronology and exposition to interrupt temporarily our consideration of the mechanism of animal defense against bacteria as such. Bacteria that have gained entrance to the body are harmful, not only because they increase rapidly in numbers when unrestricted, but because they eliminate harmful products. These harmful products may be either simple chemical substances like acids and alkalies, bacterial proteins, known as ptomains, or more particularly, in certain instances, true bacterial toxins. Toxins are albuminoid substances, of unknown chemical constitution, which are specific both in their origin and in the effect they produce. They are endowed with certain other recognizable characteristics; they produce their harmful and specific effects only after a period of incubation; they are readily destroyed by heat; they act in very small doses; and lastly, as we shall presently see, they produce antitoxins. Pasteur, as early as 1880, noted that old bouillon cultures of the *Bacillus avisepticus* which had been filtered free from bacteria would, on injection into animals, produce symptoms of narcosis. In 1888 Roux and Yersin[12] described a toxin found in filtered cultures of the diphtheria bacillus which was fatal for guinea-pigs in very small doses. Although the possibility of specific protection from bacterial invasion by means of previous treatment with killed or modified bacterial cultures was then known, attempts at a similar protection against this diphtheria toxin were at first unsuccessful. In the following year Kitasato succeeded in obtaining a pure culture of the tetanus bacillus and in 1890 von Behring and Kitasato[13] obtained tetanus toxin from such cultures. They found furthermore that by treatment with certain chemical substances the toxins of diphtheria and of tetanus could be weakened so as to be better supported by laboratory animals; animals treated with these weakened toxins became immune from doses of the whole toxin that were fatal to the normal animal. And, more important still, it was shown that the blood of such actively immunized animals would protect normal animals against subsequent injection of fatal doses of toxin, or would even cure, within reasonable time limits, animals that had already received the toxin. These experiments form the rational basis for the present highly effective antitoxin treatment of diphtheria and for the prevention of tetanus.

The interesting studies of Ehrlich[14] as to the mode of interaction of antitoxin with toxin not only gave rise to an enormously ingenious and fruitful theory of immunity but determined the recognized method of estimating and standardizing, by the use of guinea-pigs, the exact curative value of diphtheria antitoxin. We need not concern ourselves with the theories of antitoxin effect, as their interest, although of ultimate utilitarian value, is immediately largely academic. In addition to the better studied toxins of diphtheria and tetanus, true toxins have been described as formed by cholera vibrios, the bacillus of meat poisoning (*B. botulinus*), the dysentery bacillus of Shiga and the *Bacillus typhosus*. The exact relation of each of these latter toxins to pathogenesis of the disease in question is not fully determined nor can any final word be given as to the efficacy of an antitoxin treatment in many of these instances. In the case of the dysentery bacillus, at least, almost certain results may ultimately be expected from specific antitoxin therapy.

ACQUIRED IMMUNITY FROM BACTERIA

Reference has already been made to the important discovery of Pasteur that animals could be immunized by means of cultures of diminished virulence. In 1886 Salmon and Smith[17] showed that pigeons could be immunized against the hog cholera bacillus by means of cultures that had actually been killed by heat. In 1888 Richet and Hericourt[18] proved that this antibacterial type of immunity is transferable from one animal species to another. Von Behring and Nissen[19] demonstrated (1890) that the blood-serum of guinea-pigs that had been immunized against the *Vibrio metchnikovi*, would kill these micro-organisms better *in vitro* than would the serum of normal guinea-pigs.

[19] v. Behring and Nissen: Ztschr. f. Hyg., 1890, viii, 412.

The extreme interest that greeted the discovery of the antitoxins led at first to a misconception of the mechanism of the protection afforded animals by the inoculation of bacterial cultures. It was at once supposed that in the majority of instances, for example, in the immunity against spirilla, the protection was antitoxic. In 1894, however, Pfeiffer[20] began his studies with cholera infection and immunity which led to a revolution in our conception of acquired immunity from bacteria. Pfeiffer injected cholera spirilla into the peritoneal cavity of guinea-pigs that had been immunized by means of subcutaneous inoculations of this micro-organism. Whereas in the normal peritoneum the spirillum increases rapidly in numbers and leads to a fatal infection, in the immunized peritoneum the vibrios are found to undergo rapid lysis; preparations made at intervals from the peritoneal exudate show increasing numbers of deep-staining granules which finally replace the normal vibrios entirely. Coincidentally with this "bacteriolysis" the animal recovers. Pfeiffer further showed that although his serum obtained from immunized guinea-pigs had in itself no destructive power for the vibrios *in vitro*, it would, when mixed with them and injected into the peritoneal cavity of normal guinea-pigs lead to the specific form of lysis.

Bordet[21] was first to offer the correct explanation of "Pfeiffer's phenomenon," as it is called. He found that if the anticholera serum was employed soon after removal from an immunized guinea-pig it would suffice alone to destroy the vibrios in the test-tube. Heating to 55 C. or conservation for several days destroyed this lytic property, but the property could be restored to the inactive cholera serum by the addition of fresh normal guinea-pig serum which in itself has no lytic property. In other words, the specific lytic effect of anticholera serum is due to the cooperation of two substances, one of which occurs in all fresh normal serums, is destroyed by heat, is non-specific and is identical with Buchner's alexin (Ehrlich's complement). The second substance, the *substance préventive* or *substance sensibilisatrice* (Ehrlich's amboceptor) as Bordet called it, is specific, occurs only as the result of immunization, and resists heating to 55 C.

The further investigation of the finer interaction of these two substances concerned in bacteriolysis was rendered possible by Bordet's discovery of the artificial hemolysins in 1898.[22] Bordet found that the blood-serum of guinea-pigs that have received several injections of rabbit blood acquires the property of specific destruction of rabbit red blood-cells. He was further able to show that this corpuscle destruction or hemolysis is also brought about by the combined action of alexin with a specific sensitizer. These fundamental facts have since been amplified to an extraordinary extent by the studies both of Bordet and of Ehrlich and his school.[23] Anti-hemolysins, composed in turn of antialexin and antisensitizer, have been described and their study has given great insight into the action of the antibodies in general. Ehrlich's explanation of the interaction of antibodies and their antigens has been on the line of organic chemical reactions, whereas Bordet has persistently favored an explanation in harmony with the laws of physical and later of colloidal chemistry. There is now little doubt that the colloidal theory best agrees with the facts.

Many other questions of at first academic and of later practical interest have arisen from the studies on bacteriolysins and hemolysins. Thus the dispute between Bordet and Ehrlich as to the unity or the multiplicity of alexins gave rise to Bordet's "reaction of fixation" which has served as a most valuable diagnostic test of bacterial infections and has been particularly exploited in Wassermann's test for syphilis. A study by Bordet and Gay[24] in refutation of Ehrlich's conception of the sensitizer as an amboceptor led to the conglutination reaction which promises much as a method of serum diagnosis.[25]

As may well be conceived the explanation of acquired anti-infectious immunity on purely humoral lines is certainly suggested by the work of Pfeiffer, Bordet and Ehrlich and such explanation would seem to be in essential disagreement with Metchnikoff's phagocytic theory as applied to this type of immunity. The disagreement is, however, more apparent than real. Metchnikoff soon pointed out that Pfeiffer's phenomenon of extracellular bacteriolysis is exceptional and occurs practically only with such delicate micro-organisms as the vibrios. In even this instance Metchnikoff believes that the lysis is preceded by a destruction of leukocytes, which liberates the cytase or alexin from them into the surrounding fluid.

But even though it becomes generally accepted, as seems likely, that all alexin is derived from leukocytes the relation of Bordet's sensitizer to phagocytosis in acquired immunity remains to be explained. It is admitted that the sensitizer of immune serum is free even in the plasma and in no sense an artificial product, as may be the case with alexin. The work of Denys and his pupils, which began in 1895,[26] threw the first light on this important question. Denys studied the protective and curative effect of an antistreptococcus serum on rabbits that had been infected with the streptococcus. He finds that the immunity afforded by this serum is due to its effect on the micro-organisms which renders them more readily taken up by phagocytes; the leukocytes themselves in the immunized animals do not differ from those of the normal animal. In 1902 Savtchenko[27] noted that a hemolytic serum likewise increases the susceptibility of the specific red blood-cells to phagocytosis. Neufeld and Rimpau[28] have followed the lead suggested by Denys and worked out with great care the effect of their "bacteriotropins," by which name they designate those substances in an immune serum which favor phagocytosis.

In 1903 A. E. Wright[29] described under the name of "opsonins" certain substances in the serum of human beings which when estimated quantitatively are supposed to indicate the intensity of the resistance of the individual to a given infection. Wright was able apparently to increase these protective opsonins, in case of lack, by "vaccination" with killed cultures of the micro-organism in question. Although Wright's work has the merit of attracting attention to the principle of cure by vaccination it is marred from a scientific standpoint by his failures to recognize the relation of his "opsonins" to the substances described by Denys, and particularly by the lack of fundamental experimental work on animals which subsequently in the hands of others has given us a more judicious attitude towards the theoretical and practical interest of his discovery. Animal experimentation has shown that even under the best experimental conditions, little value can be ascribed to Wright's "opsonic index" as an indication for specific treatment, grateful as such a method would be if accurate. Experimental work has further shown that the "immune opsonins" of Wright are probably identical with the "bacteriotropins" of Neufeld and Rimpau and probably differ quantitatively only from Wright's normal opsonins. Although Wright's first observations, which were not made under the best experimental conditions, led him to believe that his opsonins differed from the sensitizers of Bordet (Ehrlich's amboceptors) inasmuch as they are apparently thermolabile (55 C.), there now seems no reason for this artificial separation.

[29] Wright, Sir A. E.: Studies in Immunization, Constable, 1909.

The following summary is, I believe, consistent with the facts at our disposal and is offered as a simple explanation of anti-infectious immunity. Bacteria are destroyed in the body of an immune animal by the action of two substances, the sensitizer which is the specific result of immunization, and which lies free in the plasma, and the alexin which under usual conditions in the body lies within the phagocyte. If phagocytosis has taken place the alexin works *in situ;* if phagolysis occurs the alexin is liberated and acts in the fluid extracellularly. There is, further, reason to believe that the more potent the sensitizer the more likely it is that phagolysis should occur, and in all events the greater the sensitization is the less the alexin required.

In vitro the bacteria are destroyed in a similar manner except that under such conditions when fresh serum is employed free alexin is the rule. When the alexin employed has been retained in the phagocyte as in the case in opsonin experiments, the destruction is intracellular subsequent to phagocytosis. The reason that normal opsonins are apparently thermolabile is because the normal extracellular alexin is destroyed and the normal opsonin (sensitizer) is not sufficiently potent to draw out the intracellular alexin or to cause the opsonized bacterium to be drawn within the cell. The destruction of the extracellular alexin is immaterial, however, in the case of immune opsonins (bacteriotropins) as their strong sensitizing power either makes use of a trace of alexin liberated by the phagocytes or else suffices to draw the treated bacteria within the cell.

The discovery of the artificial hemolysins gave rise to the hope that specific immune serums for other animal cells might be produced. The possibility of a specific epitheliolysin was particularly alluring in view of treatment of malignant tumors. The general conception of the cytolysins now is that they are specific for any cell of the species that has furnished the antigenic tissue rather than for any particular type of cell.

At this point may be mentioned certain other properties of immune serums that were discovered in connection with the studies on bacteriolysis and hemolysis. Charrin and Roger[30] noted as early as 1889 that a specific serum which was active against *B. pyocyaneus* would clump cultures of this bacterium and the specific nature of this phenomenon of agglutination and many of the factors that control it were worked out by Bordet in 1895.[31] The applicability of the agglutination reaction in the diagnosis of bacterial infections was exploited by Gruber and Durham in 1896.[32] The early work of Kraus, 1897,[33] of Tschowitsch[34] and of Bordet, 1899[35] with bacteriolytic and hemolytic serum disclosed the specific phenomenon of precipitation, which was soon applied in the well-known forensic test for blood by Wassermann and by Uhlenhuth.

In concluding this outline of the development of immunology mention should be made of the interesting phenomenon of anaphylaxis or increased susceptibility, which under certain conditions follows injection of harmful proteins such as bacteria or of non-toxic proteins like horse serum. Rosenau and Anderson[36] and Otto[37] (1906) were first to draw attention to this condition, although it had been previously described and named by Richet. Rosenau and Anderson described the violent convulsive reaction, frequently followed by death, which follows the injection of horse serum in guinea-pigs that have previously received a minute dose of the same substance. Similar reactions have been studied following injections of bacteria. This extraordinary condition, which is apparently the opposite of the protective reactions of immunity, bears some mysterious but undoubted relation to the latter process. Although the outcome of the numerous studies on the relation of anaphylaxis to immunity now in progress are doubtful, little doubt may be entertained as to their theoretical interest and practical importance.

CONCLUSION

This article has attempted to outline step by step the development of immunology, a science worthy of specialized consideration both on account of its biological interest and its vital applicability. Nothing more than a suggestion of the application of immunology has been given. It has been evident that no true conception of the principles of immunity was possible until the methods of experimentation on living animals were applied. And each successive principle determined has of necessity depended on further animal experimentation. The sacrifice of animal life necessitated in acquiring our present knowledge of the mechanism of animal resistance to disease would seem justified from the standpoint of theory alone. In view of the present and potential value of applied immunology in the diagnosis, the prevention, and the cure of human and animal disease, skilled animal experimentation necessitates the encouragement of every humanitarian.

Differential Diagnosis of Traumatic Neurasthenia.—Head injuries and railway accidents causing cerebral commotion, without producing actual brain lesions, may set up a traumatic neurasthenia, but general paralysis of the insane not infrequently follows a head injury in an individual predisposed by his past life to that disease, and it may be difficult to decide whether the patient is suffering from traumatic neurasthenia or the prodromal stage of general paralysis, unless a careful examination and investigation be made.—F. W. Mott, in the *Practitioner.*

TRANSFUSION IN PELLAGRA

A REVIEW OF TWENTY CASES *

H. P. COLE, M.D.
MOBILE, ALA.

August 4, 1908, I employed the first transfusion in the terminal stages of pellagra. Encouraged by the immediate improvement and rapid recovery in this patient, in collaboration with Dr. Gilman J. Winthrop, I have since transfused nineteen additional patients in the terminal stages of the disease.

Whereas we are unable to draw positive conclusions from this number of cases, we believe that certain valuable deductions may be derived from the statistics which they present. We have endeavored to preserve a spirit of scepticism and unbiased judgment throughout our investigations, and to draw accurate conclusions from the data presented.

Transfusion has been resorted to only in cases in the last stages of pellagra, or steadily retrograding under prolonged and careful treatment by approved therapeutic measures. To illustrate the type of cases in which transfusion has been employed, it is sufficient to state that two patients were moribund at the time of operation, and one patient died on the railway train twenty minutes before arriving at Mobile for transfusion.

	Cases
Transfused	20
Females, aged 22-53	16
Males, aged 3-42	4

We note that the females (16, or 80 per cent.) were four times as numerous as the males (4, or 20 per cent.).

	Cases
Recoveries (60 per cent.)	12
Deaths (40 per cent.)	8
Relapse (8 3 per cent.)	1

This relapse occurred two years after recovery in an institutional patient exposed to reinfection.

	Cases
Temporary improvement followed by death	2
No improvement following transfusion	6
Complications incompatible with recovery	2

Patient 1, a male, aged 42, whose case was complicated with tuberculous peritonitis, showed temporary improvement for several days, but died one month after the operation.

Patient 2, a male, aged 3, showed distinct improvement following transfusion, but died eight days later from intestinal perforation.

	Cases
Complications presenting insufficient flow of blood, followed by death	2

In Case 1 the only available donor permitted insufficient transfusion through a severe degree of arteriosclerosis. In Case 2 inadequate operative surroundings and a neurotic 14-year-old boy as the only available donor permitted insufficient transfusion.

	Cases
Patients moribund at operation followed by death	2

It will be noted that four of the eight cases in which death resulted might well be excluded, for the following reasons: Two patients received an inadequate amount of blood at transfusion and two were moribund at the time of operation. Excluding these four cases, the mortality rate would be 25 per cent. as compared with 40 per cent. in the entire series. Considering the grave mortality rate in the type of patients on whom transfusion was performed, we can but feel that our mortality rate of 40 per cent. in the entire twenty cases compares most favorably with the mortality (80 to 90 per cent.) in this type of cases treated by other therapeutic procedures. We have been unable to observe that transfusion was a direct factor of death in any of the cases; the deaths followed in periods of from three hours to one month after operation. One patient manifested symptoms of cocainism, necessitating a termination of transfusion at the end of fifteen minutes. This patient, however, made an excellent recovery from pellagra. Neither hemolysis nor agglutination, thrombosis nor embolism, have been observed in any of the cases.

Of the recovered patients (seventeen) there were: females, eleven (68.8 per cent), and males, one (25 per cent). We note a far greater percentage of recovery in the females. All the recovered patients presented distinct and severe lesions of pellagra; there were marked emaciation, asthenia, anemia, reflex excitability, and in many cases grave mental changes. Severe pellagra erythema, stomatitis, and diarrhea were present in a majority of the cases. Within a few days after transfusion there was either alleviation or disappearance of all the symptoms of pellagra; there was a rapid disappearance of the pellagra erythema, stomatitis and diarrhea, and also a gradual alleviation of the mental and nervous symptoms. In several cases there was an astonishing improvement in the patient's mental condition, shortly following operation. In all cases there was rapid increase in the patient's hemoglobin index, a rapid return of body strength, a return of digestive faculties, and an increase of body weight. All the recovered patients gained from three to eight and one-half pounds in the first week following transfusion; one patient gaining thirty-four pounds within eleven weeks. All the recovered patients have returned to a normal condition within from one to four months after operation; several are in better physical condition than they have presented for years. The patient relapsing two years after transfusion was living in an institution and was constantly exposed to pellagra, and it is fair to assume that this case may be considered a re-infection, rather than a relapse.

It is but just to state that all approved therapeutic procedures were employed in the recovered cases, both previous to and following the operation. As these procedures were employed without beneficial effect previous to the operation, it is fair to asume that they were unimportant factors in the recoveries after transfusion.

We have been unable to ascertain a constant clinical sign that would indicate a certainty of recovery following transfusion. A moribund state of the patient and complication of pellagra with pathologic conditions contra-indicate the employment of transfusion. The necessity of resorting to transfusion can be ascertained only on the appearance of positive signs of retrogression under approved institutional and constitutional therapeutic agents.

A majority of the patients referred for transfusion have recovered through hygienic, supportive treatment, not necessitating the employment of transfusion.

Transfusion, itself a delicate procedure, should be attempted only by those experienced in the technic, with a full knowledge of the dangers of the operation, and in adequate surroundings for its performance, and with the proper post operation treatment.

In these transfusions we have endeavored to employ donors who have lived in the same environment as the recipients, assuming that such donors who have not contracted pellagra possess a certain degree of immunity.

Transfusion was resorted to from donors who had recovered from pellagra in three cases; recovery occurred in one case (33⅓ per cent.). This case relapsed two years following transfusion.

Transfusion was made from donors who had never had pellagra in seventeen cases; recovery ensued in eleven cases (64.7 per cent.).

---

* Read before the Southern Surgical and Gynecological Association, Nashville, Tenn., Dec. 15, 1910.

We may assume that there is, at least, no preference of a donor who has had pellagra over a donor who has never had pellagra.

Transfusion was resorted to from donors who were relatives of the patient, but who had never had pellagra, in seven cases. Recovery occurred in three cases (42.8 per cent.).

Transfusion was made from donors who were not relatives and who had never had pellagra in ten cases; recovery in eight cases (80 per cent.).

Here we may assume, at least, that there is no ground for preference of the use of a relative over the use of a non-relative.

We are unable to state from the statistics available that there is any immune principle transferred by transfusion. It is probable that any beneficial results obtained may be attributed to the relief of the existing anemia, permitting the patient's organism to approach its normal functional activities and thus to combat the progress of the disease.

CONCLUSIONS

In transfusion in twenty cases of pellagra, we have found no ill effect resulting to the patients directly from the operation. We may safely resort to transfusion in the severe type of case, steadily retrogressing under approved therapeutic procedures.

We have noted no advantage in the employment of a donor who has recovered from pellagra as compared with the donor who has never had pellagra.

There is apparently no advantage in the use of a relative for a donor as compared to the use of a non-relative.

The recoveries (60 per cent.) following transfusion in the grave type of cases, compares most favorably with the recoveries (10 to 20 per cent.) in the same type of cases in which other therapeutic measures are employed.

The employment of transfusion in the terminal stages of pellagra must be undertaken with a full knowledge of the difficulties and dangers of the operation. Without careful selection of the cases and unprejudiced conclusions, this procedure will fall into an undeserved ill repute.

EXPERIMENTAL POLIOMYELITIS IN MONKEYS

NINTH NOTE: IMMUNITY PRINCIPLES; EFFECTS OF HEXAMETHYLENAMIN (UROTROPIN); EARLY DIAGNOSIS; VIRUS-CARRIERS*

SIMON FLEXNER, M.D.
AND
PAUL F. CLARK, Ph.D.
NEW YORK

In previous publications,[1] we have shown that an attack of experimental poliomyelitis protects against reinfection with the virus of the disease, and that the blood of monkeys and of persons who have recovered from the acute effects of epidemic poliomyelitis contains neutralizing principles for the virus on which their immunity must be considered to depend. The immunity principles have been shown to reside in the blood-serum and are, therefore, probably of the nature of antibodies. The course of epidemic poliomyelitis in its acute stage is not known to be influenced by any form of medication, whence it follows that it is a self-limiting process, as are so many of the infections; and at present we must view this condition of self-limitation as being determined by the elaboration within the body, under the influence of the virus of the disease, of substances of the nature of antibodies, the so-called immunity principles.

IMMUNITY PRINCIPLES IN ABORTIVE CASES

What have come to be designated abortive cases of epidemic poliomyelitis are now playing an important part in the discussion of the mode of transmission of the disease. Our knowledge of this class of cases is still very imperfect, and doubt even exists of their occurrence at all. Until greater refinement and accuracy are introduced into diagnosis, this doubt must continue to arise. It is desirable, therefore, to present evidence that bears on the occurrence of this type of the disease.

It is possible by means of neutralization tests to determine in a given instance whether an attack of poliomyelitis was or was not suffered, and this independently of the circumstance whether or not paralysis was present. The test is made by mixing the blood-serum with the filtered virus, incubating the mixture at 37 C. for a few hours, and injecting it into a monkey. Normal human serum has no power to neutralize the virus, while the serum from recovered cases of poliomyelitis possesses this power. Dr. Richard Stein, of New York, kindly supplied us with the blood taken from a patient suspected of having passed through such an abortive attack, in which the neutralizing immunity principles were demonstrated. This method does not provide a means of diagnosis, but it is of value in establishing the occurrence of abortive cases of epidemic poliomyelitis.

DISTRIBUTION OF IMMUNITY PRINCIPLES

Up to the present, the immunity principles have been established to exist in the blood of men and monkeys who have passed through the acute stage of the disease. We have already emphasized the lesions of the leptomeninges that result from infection with the virus of poliomyelitis and the changes, corresponding to them, that take place in the cerebrospinal fluid. It is of interest to ascertain whether or not the immunity principles exist in the cerebrospinal fluid, whether or not they may originate there, and, hence, whether or not the control of the lesions of the meninges and the nervous tissues is in any degree dependent on such a local production. We are enabled to determine these points by reason of the circumstance that the secretion of antibodies from the blood into the subdural space and the cerebrospinal fluid takes place, under normal conditions, practically not at all. Should they be found there, they must either have arisen locally, or have been secreted there from the blood because of abnormalities that increase the permeability of the blood-vessels.

We have examined a number of specimens of the cerebrospinal fluid obtained from patients at various periods after the disappearance of the acute stages of poliomyelitis, but at times when paralysis of one or more extremities still persisted. In some instances, the blood and cerebrospinal fluid were taken simultaneously and both tested for neutralizing power. The results are instructive. During the first one or two months, the immunity principles may exist both in the blood and in the cerebrospinal fluid, but, even at this early period, the principles demonstrated to be present in the blood have not always been detected in the fluid. At later

EXPERIMENTAL POLIOMYELITIS IN MONKEYS

NINTH NOTE: IMMUNITY PRINCIPLES; EFFECTS OF HEXAMETHYLENAMIN (UROTROPIN); EARLY DIAGNOSIS; VIRUS-CARRIERS*

SIMON FLEXNER, M.D.
AND
PAUL F. CLARK, Ph.D.
NEW YORK

In previous publications,[1] we have shown that an attack of experimental poliomyelitis protects against reinfection with the virus of the disease, and that the blood of monkeys and of persons who have recovered from the acute effects of epidemic poliomyelitis contains neutralizing principles for the virus on which their immunity must be considered to depend. The immunity principles have been shown to reside in the blood-serum and are, therefore, probably of the nature of antibodies. The course of epidemic poliomyelitis in its acute stage is not known to be influenced by any form of medication, whence it follows that it is a self-limiting process, as are so many of the infections; and at present we must view this condition of self-limitation as being determined by the elaboration within the body, under the influence of the virus of the disease, of substances of the nature of antibodies, the so-called immunity principles.

IMMUNITY PRINCIPLES IN ABORTIVE CASES

What have come to be designated abortive cases of epidemic poliomyelitis are now playing an important part in the discussion of the mode of transmission of the disease. Our knowledge of this class of cases is still very imperfect, and doubt even exists of their occurrence at all. Until greater refinement and accuracy are introduced into diagnosis, this doubt must continue to arise. It is desirable, therefore, to present evidence that bears on the occurrence of this type of the disease.

It is possible by means of neutralization tests to determine in a given instance whether an attack of poliomyelitis was or was not suffered, and this independently of the circumstance whether or not paralysis was present. The test is made by mixing the blood-serum with the filtered virus, incubating the mixture at 37 C. for a few hours, and injecting it into a monkey. Normal human serum has no power to neutralize the virus, while the serum from recovered cases of poliomyelitis possesses this power. Dr. Richard Stein, of New York, kindly supplied us with the blood taken from a patient suspected of having passed through such an abortive attack, in which the neutralizing immunity principles were demonstrated. This method does not provide a means of diagnosis, but it is of value in establishing the occurrence of abortive cases of epidemic poliomyelitis.

DISTRIBUTION OF IMMUNITY PRINCIPLES

Up to the present, the immunity principles have been established to exist in the blood of men and monkeys who have passed through the acute stage of the disease. We have already emphasized the lesions of the leptomeninges that result from infection with the virus of poliomyelitis and the changes, corresponding to them, that take place in the cerebrospinal fluid. It is of interest to ascertain whether or not the immunity principles exist in the cerebrospinal fluid, whether or not they may originate there, and, hence, whether or not the control of the lesions of the meninges and the nervous tissues is in any degree dependent on such a local production. We are enabled to determine these points by reason of the circumstance that the secretion of antibodies from the blood into the subdural space and the cerebrospinal fluid takes place, under normal conditions, practically not at all. Should they be found there, they must either have arisen locally, or have been secreted there from the blood because of abnormalities that increase the permeability of the blood-vessels.

We have examined a number of specimens of the cerebrospinal fluid obtained from patients at various periods after the disappearance of the acute stages of poliomyelitis, but at times when paralysis of one or more extremities still persisted. In some instances, the blood and cerebrospinal fluid were taken simultaneously and both tested for neutralizing power. The results are instructive. During the first one or two months, the immunity principles may exist both in the blood and in the cerebrospinal fluid, but, even at this early period, the principles demonstrated to be present in the blood have not always been detected in the fluid. At later

---

* From the Laboratories of the Rockefeller Institute for Medical Research.

[1] The previous work is summarized and discussed by one of us (Flexner) in The Journal A. M. A., Sept. 24, 1910, p. 1105.

periods and after one or more years, it is highly exceptional to secure neutralization of the virus by means of the fluid. The conclusion, therefore, is that during the earlier stages of epidemic poliomyelitis, when the blood-vessels of the leptomeninges and the central nervous system are abnormally pervious, the immunity antibodies escape into the membranes and nervous tissue; but as the vessels return to normal, the antibodies are no longer secreted and thus tend to disappear. It is probably in exceptional instances only, in which the vascular repair is delayed, that the secretion continues over a long period of time.

The immunity principles persist in the blood for several years, and it is probable, therefore, that they are elaborated in the situations, namely, in the lymphatic and blood-forming organs, in which antibodies in general are prepared. This point is of interest in view of our meager knowledge of the occurrence of the virus of poliomyelitis in organs at a distance from the central nervous system. In view of the facts stated, it may be deduced that to the circulating antibodies, rather than to those locally present in the cerebrospinal fluid, are due the limitation and repair of the damage inflicted on the nervous system by the infection, and the enduring protection of the body from reinfection.

EFFECTS OF HEXAMETHYLENAMIN

Since Cushing and Crowe showed that hexamethylenamin (urotropin) is in part eliminated into the subdural space, the drug has been employed to produce disinfection of the cerebrospinal fluid. It has been applied to the treatment of epidemic poliomyelitis by Dr. Roger S. Morris, of Baltimore, who first drew our attention to the matter, and by others. It is highly difficult, if not impossible, to determine clinically in human beings whether its administration is of any value, since its use has been empiric and it is clearly not a specific. However, it may still not be without a degree of beneficial action.

The drug is well borne by the monkey and we have tested its action under a variety of conditions on this animal. When a large dose of the drug is administered by mouth, its presence can be demonstrated by chemical tests in the cerebrospinal fluid soon afterwards. We have ascertained that when the virus of poliomyelitis is injected intracerebrally in monkeys in which the hexamethylenamin is already present in the fluid, and the drug is then administered by mouth daily thereafter, that in a proportion of animals so treated, but not in all, first, the incubation period of the disease is prolonged (from six to eight days to twenty-four days), and, next, the onset of paralysis is entirely prevented. When the drug is administered by mouth and the immune monkey-serum by injection into the subdural space, the paralysis can also be prevented and possibly with greater certainty.

We have not yet determined whether the animals surviving infection with the virus as a result of the administration of hexamethylenamin exhibit any greater resistance to reinoculation than untreated animals do to a primary inoculation. Should the multiplication of the virus have been entirely suppressed, we should not expect to find an increased degree of resistance. In immune serum protection, the susceptibility to reinfection is about equal to that shown by untreated animals.

In considering the significance of these observations, two points are of importance: first, it has now been shown that drug control of the virus of poliomyelitis within the body is a possibility; but, second, that the successful results have been secured in inhibiting infection and not in restraining an already established infection with the virus.

EARLY DIAGNOSIS

The importance of securing methods of early and certain diagnosis of epidemic poliomyelitis is self-evident. With the growing significance of the abortive and mild cases in disseminating the infection, and with the increasing promise of a better therapeutic control of the disease, early diagnosis becomes a necessity. We have already pointed out that by taking advantage of the changes which regularly take place in the cerebrospinal fluid, it is possible, early in the course of the infection, to arrive at a certain diagnosis. We based this view and recommendation on the condition of the cerebrospinal fluid occurring in monkeys successfully inoculated with the virus of poliomyelitis. In these animals the increase in cells and protein takes place and reaches its height prior to the onset of the paralysis, after which there tends to be a rapid diminution in the protein content of and a slower reduction in the number of cells within the fluid. The cerebrospinal fluid is incorrectly described as "clear" in the beginning stages of the lesions of the meninges; and this error has arisen because practically all the examinations have been made after the appearance of the paralysis or other severe symptoms, and usually many days after their appearance.

The cerebrospinal fluid at the height of the lesions in the meninges exhibits a very slight turbidity or opalescence, best seen on gently agitating the fluid and due to a large increase in white corpuscles. It contains an excess of protein matter. The white corpuscles consist partly of polymorphonuclear and partly of mononuclear (lymphatic) cells. The excess of protein is readily detected by applying Noguchi's butyric acid test. Very rarely, the fluid is distinctly turbid and the polymorphonuclear cells predominate. Bacteria are absent. In rare instances, it becomes necessary to exclude tuberculous meningitis, which can be done by an examination for tubercle bacilli.

We have been able in a case of Dr. L. F. Frissell's[2] to determine that the facts just stated hold good also for human beings, the victims of epidemic poliomyelitis. An early and certain diagnosis of the disease in a suspicious instance has been made by examining the cerebrospinal fluid in the manner indicated. The paralysis was observed to follow the height of the cellular and protein changes in the fluid, and the cessation of the extension of the paralysis to coincide with a beginning reduction in these changes, as is the case in the monkey.

VIRUS-CARRIERS

In monkeys the virus of epidemic poliomyelitis passes from the meninges into the nasal mucosa, and infection can be readily achieved by bringing the virus into contact with the scarified mucous membrane. We have, therefore, suggested that the nasopharynx acts in human beings as the portal of entry of the virus into the central nervous system, as well as the source of its dissemination to other human beings. Concerning the habitat of the virus in nature, outside of infected persons, we have had no definite knowledge. The determination by Osgood and Lucas[3] that the virus can survive in the nasopharynx of the monkey for nearly six months and long after the acute stage of the disease has passed has, therefore, high significance with reference to the epidemiology of the disease. At this late period, the virus no longer survives in the nervous system. Indeed, the virus has not been detected in the nervous system after the lapse of three or four weeks, and often not after the first few days following the appearance of the paralysis. We have just demonstrated the virus in the nasal and pharyngeal mucosa of a monkey which survived the paralysis more than four weeks, and failed, in the same animal, to detect it in the spinal cord.

---

[2] Report to be published soon.

[3] THE JOURNAL A. M. A., Feb. 18, 1911, p. 495.

These observations indicate that monkeys successfully inoculated become, in some instances after recovery from the effects, passive carriers of the virus. Whether the same fact will prove to be true of human beings remains to be determined. *In no instance has the nasal and pharyngeal mucosa of a person who has succumbed to epidemic poliomyelitis been examined for the virus.* It has now become imperative to make such examinations: for on the results will depend in considerable degree the measures which will come to be adopted to control the spread of the infection.

CULTIVATION IN VITRO OF RAT SARCOMA

A STUDY IN IMMUNITY*

R. A. LAMBERT, M.D., AND F. M. HANES, M.D.
NEW YORK

In a recent note[1] we showed that the method of cultivating tissues *in vitro*, devised by Harrison for the study of the developing nerve-fiber in frog embryos, and applied with modifications to the tissues of higher animals by Carrell and Burrows, could be adapted easily to the transplantable sarcomata of rats and mice. The present paper is concerned with the application of this method to the investigation of the nature of tumor immunity.

The phenomena of resistance and susceptibility to the inoculable tumors of these animals have been exhaustively studied. It may be stated summarily that immunity to tumor growth does not correspond to any of the types of immunity produced by the reaction of the body to infective organisms and their products. Specific antibodies have never been demonstrated in the blood-serum of animals immune to cancer. Moreover, Russell[2] has shown that, in immune mice, inoculated cancer tissue fails to grow because of the absence of a specific stroma reaction on the part of the host, and not because of the presence of cytotoxic or cytolytic substances acting on the implanted grafts. Or, stated differently, in immune animals, the implanted cancer cells lose their power of calling forth a stroma reaction. Nothwithstanding the absence of a stroma, the tumor cells remain alive and proliferate for eight to ten days.

Sarcoma cells growing in blood-plasma find in the fibrin network an artificial stroma, so that the influence of the plasma alone may be held accountable if sarcomatous tissue, which grows very readily in normal plasma, fails to grow in the plasma of immune animals.

Two kinds of immunity to cancer are recognizable, natural and artificial. The percentage of naturally immune animals (nullers) varies with age and with different varieties and strains. Old animals are, as a rule, less susceptible than young. Artificial immunity may be induced by the injection of suitable quantities of certain tissues, as, blood, spleen, embryonic tissues, etc.

In the present experiments we have used five types of immune animals: (1) nullers from a strain of rats in which sarcoma inoculations yield 80 to 90 per cent. of "takes"; (2) nullers from a hooded variety of rats in which the percentage of "takes" is only twenty to thirty (racial immunity); (3) immune old animals whose immunity was most probably attributable to their age; (4) animals immune to both rat sarcoma and carcinoma, and which had received immunizing doses of mouse sarcoma (pan-immunity); and (5) artificially immunized rats. We have used the plasma from animals of each of these five types of immunity, and have found that rat sarcoma grows in all without exception. The character of growth differed in no essential way from that observed in control specimens in which normal rat plasma was used. These results are in harmony with the observations of Russell which we have mentioned already.

THE INOCULATION OF RATS WITH SARCOMA GROWING IN VITRO

To test the viability of sarcomatous tissue growing *in vitro*, we have inoculated rats with pieces of sarcoma which had grown for three days at 37 C. in normal rat plasma and have obtained tumor growths. In the same way sarcoma growing in the plasma of immune rats has been transmitted to normal animals. The plasma from immune animals does not seem, then, in this short time, to influence deleteriously the subsequent growth of sarcoma tissue when this is inoculated into animals.

SUBCULTURES

Sarcoma growing *in vitro* may be readily grown in subcultures by transferring the original piece or a portion of the outgrowth to new plasma. Prolongation of life seems dependent only on the renewal of the medium. We have specimens growing at present which have been subcultured in this manner five times at intervals of two to four days. The plasma used was obtained from normal and immune animals, and the growth was as vigorous in the one as in the other.

Local Cutaneous Reaction to Sodium Glycocholate in Syphilitics.—Loeper and Desbouis state that intradermal injection of a drop or two of a 0.5 or 0.2 per cent. solution of sodium glycocholate failed to cause any reaction in sixty-three healthy persons or those with non-venereal affections, while a pronounced local reaction followed invariably in eighty-one persons in the first, second or third stage of syphilis, with only a single exception in the latter class. A positive reaction was also obtained in one of nine patients with tabes dorsalis or paresis. The local erythema or ulceration developed from the eighteenth to the thirty-sixth hour and persisted for from two to five days. The findings with this "dermo-reaction," as they call it, paralleled with precision the Wassermann reaction and the Porges precipito-reaction. As there is nothing specific about the sodium glycocholate, the reaction, they state, merely indicates some profound biologic modification of the organism by the parasite and, like all biologic reactions, is not of invariable occurrence. It gave useful information in their experience in several dubious cases, differentiating the syphilitic from tuberculous and other ulcerations, etc. Their communication is published in the *Progrès Médical*, Jan. 21, page 231.

periods and after one or more years, it is highly exceptional to secure neutralization of the virus by means of the fluid. The conclusion, therefore, is that during the earlier stages of epidemic poliomyelitis, when the blood-vessels of the leptomeninges and the central nervous system are abnormally pervious, the immunity antibodies escape into the membranes and nervous tissue; but as the vessels return to normal, the antibodies are no longer secreted and thus tend to disappear. It is probably in exceptional instances only, in which the vascular repair is delayed, that the secretion continues over a long period of time.

The immunity principles persist in the blood for several years, and it is probable, therefore, that they are elaborated in the situations, namely, in the lymphatic and blood-forming organs, in which antibodies in general are prepared. This point is of interest in view of our meager knowledge of the occurrence of the virus of poliomyelitis in organs at a distance from the central nervous system. In view of the facts stated, it may be deduced that to the circulating antibodies, rather than to those locally present in the cerebrospinal fluid, are due the limitation and repair of the damage inflicted on the nervous system by the infection, and the enduring protection of the body from reinfection.

EFFECTS OF HEXAMETHYLENAMIN

Since Cushing and Crowe showed that hexamethylenamin (urotropin) is in part eliminated into the subdural space, the drug has been employed to produce disinfection of the cerebrospinal fluid. It has been applied to the treatment of epidemic poliomyelitis by Dr. Roger S. Morris, of Baltimore, who first drew our attention to the matter, and by others. It is highly difficult, if not impossible, to determine clinically in human beings whether its administration is of any value, since its use has been empiric and it is clearly not a specific. However, it may still not be without a degree of beneficial action.

The drug is well borne by the monkey and we have tested its action under a variety of conditions on this animal. When a large dose of the drug is administered by mouth, its presence can be demonstrated by chemical tests in the cerebrospinal fluid soon afterwards. We have ascertained that when the virus of poliomyelitis is injected intracerebrally in monkeys in which the hexamethylenamin is already present in the fluid, and the drug is then administered by mouth daily thereafter, that in a proportion of animals so treated, but not in all, first, the incubation period of the disease is prolonged (from six to eight days to twenty-four days), and, next, the onset of paralysis is entirely prevented. When the drug is administered by mouth and the immune monkey-serum by injection into the subdural space, the paralysis can also be prevented and possibly with greater certainty.

We have not yet determined whether the animals surviving infection with the virus as a result of the administration of hexamethylenamin exhibit any greater resistance to reinoculation than untreated animals do to a primary inoculation. Should the multiplication of the virus have been entirely suppressed, we should not expect to find an increased degree of resistance. In immune serum protection, the susceptibility to reinfection is about equal to that shown by untreated animals.

In considering the significance of these observations, two points are of importance: first, it has now been shown that drug control of the virus of poliomyelitis within the body is a possibility; but, second, that the successful results have been secured [illegible] fection and not in restraining an [illegible] infection with the virus.

EARLY DIAGNOSIS

The importance of securing methods of early and certain diagnosis of epidemic poliomyelitis is self-evident. With the growing significance of the abortive and mild cases in disseminating the infection, and with the increasing promise of a better therapeutic control of the disease, early diagnosis becomes a necessity. We have already pointed out that by taking advantage of the changes which regularly take place in the cerebrospinal fluid, it is possible, early in the course of the infection, to arrive at a certain diagnosis. We based this view and recommendation on the condition of the cerebrospinal fluid occurring in monkeys successfully inoculated with the virus of poliomyelitis. In these animals the increase in cells and protein takes place and reaches its height prior to the onset of the paralysis, after which there tends to be a rapid diminution in the protein content of and a slower reduction in the number of cells within the fluid. The cerebrospinal fluid is incorrectly described as "clear" in the beginning stages of the lesions of the meninges; and this error has arisen because practically all the examinations have been made after the appearance of the paralysis or other severe symptoms, and usually many days after their appearance.

The cerebrospinal fluid at the height of the lesions in the meninges exhibits a very slight turbidity or opalescence, best seen on gently agitating the fluid and due to a large increase in white corpuscles. It contains an excess of protein matter. The white corpuscles consist partly of polymorphonuclear and partly of mononuclear (lymphatic) cells. The excess of protein is readily detected by applying Noguchi's butyric acid test. Very rarely, the fluid is distinctly turbid and the polymorphonuclear cells predominate. Bacteria are absent. In rare instances, it becomes necessary to exclude tuberculous meningitis, which can be done by an examination for tubercle bacilli.

We have been able in a case of Dr. L. F. Frissell's[2] to determine that the facts just stated hold good also for human beings, the victims of epidemic poliomyelitis. An early and certain diagnosis of the disease in a suspicious instance has been made by examining the cerebrospinal fluid in the manner indicated. The paralysis was observed to follow the height of the cellular and protein changes in the fluid, and the cessation of the extension of the paralysis to coincide with a beginning reduction in these changes, as is the case in the monkey.

VIRUS-CARRIERS

In monkeys the virus of epidemic poliomyelitis passes from the meninges into the nasal mucosa, and infection can be readily achieved by bringing the virus into contact with the scarified mucous membrane. We have, therefore, suggested that the nasopharynx acts in human beings as the portal of entry of the virus into the central nervous system, as well as the source of its dissemination to other human beings. Concerning the habitat of the virus in nature, outside of infected persons, we have had no definite knowledge. The determination by Osgood and Lucas[3] that the virus can survive in the nasopharynx of the monkey for nearly six months and long after the acute stage of the disease has passed has, therefore, high significance with reference to the epidemiology of the disease. At this late period, the virus no longer survives in the nervous system. Indeed, the virus has not been detected in the nervous system after the lapse of three or four weeks, and often not after the first few days following the appearance of the paralysis. We have just demonstrated the virus in the nasal and pharyngeal mucosa of a monkey which survived the paralysis more than four weeks, and failed, in the same animal, to detect it in the spinal cord.

---

[2] Report to be published soon.

[3] The Journal A. M. A., Feb. 18, 1911, p. 495.

These observations indicate that monkeys successfully inoculated become, in some instances after recovery from the effects, passive carriers of the virus. Whether the same fact will prove to be true of human beings remains to be determined. In no instance has the nasal and pharyngeal mucosa of a person who has succumbed to epidemic poliomyelitis been examined for the virus. It has now become imperative to make such examinations; for on the results will depend in considerable degree the measures which will come to be adopted to control the spread of the infection.

CULTIVATION IN VITRO OF RAT SARCOMA

A STUDY IN IMMUNITY[*]

R. A. LAMBERT, M.D., and F. M. HANES, M.D.
NEW YORK

In a recent note[1] we showed that the method of cultivating tissues *in vitro,* devised by Harrison for the study of the developing nerve-fiber in frog embryos, and applied with modifications to the tissues of higher animals by Carrell and Burrows, could be adapted easily to the transplantable sarcomata of rats and mice. The present paper is concerned with the application of this method to the investigation of the nature of tumor immunity.

The phenomena of resistance and susceptibility to the inoculable tumors of these animals have been exhaustively studied. It may be stated summarily that immunity to tumor growth does not correspond to any of the types of immunity produced by the reaction of the body to infective organisms and their products. Specific antibodies have never been demonstrated in the blood-serum of animals immune to cancer. Moreover, Russell[2] has shown that, in immune mice, inoculated cancer tissue fails to grow because of the absence of a specific stroma reaction on the part of the host, and not because of the presence of cytotoxic or cytolytic substances acting on the implanted grafts. Or, stated differently, in immune animals, the implanted cancer cells lose their power of calling forth a stroma reaction. Nothwithstanding the absence of a stroma, the tumor cells remain alive and proliferate for eight to ten days.

Sarcoma cells growing in blood-plasma find in the fibrin network an artificial stroma, so that the influence of the plasma alone may be held accountable if sarcomatous tissue, which grows very readily in normal plasma, fails to grow in the plasma of immune animals.

Two kinds of immunity to cancer are recognizable, natural and artificial. The percentage of naturally immune animals (nullers) varies with age and with different varieties and strains. Old animals are, as a rule, less susceptible than young. Artificial immunity may be induced by the injection of suitable quantities of certain tissues, as, blood, spleen, embryonic tissues, etc.

In the present experiments we have used five types of immune animals: (1) nullers from a strain of rats in which sarcoma inoculations yield 80 to 90 per cent. of "takes"; (2) nullers from a hooded variety of rats in which the percentage of "takes" is only twenty to thirty (racial immunity); (3) immune old animals whose immunity was most probably attributable to their age; (4) animals immune to both rat sarcoma and carcinoma, and which had received immunizing doses of mouse sarcoma (pan-immunity); and (5) artificially immunized rats. We have used the plasma from animals of each of these five types of immunity, and have found that rat sarcoma grows in all without exception. The character of growth differed in no essential way from that observed in control specimens in which normal rat plasma was used. These results are in harmony with the observations of Russell which we have mentioned already.

THE INOCULATION OF RATS WITH SARCOMA GROWING IN VITRO

To test the viability of sarcomatous tissue growing *in vitro,* we have inoculated rats with pieces of sarcoma which had grown for three days at 37 C. in normal rat plasma and have obtained tumor growths. In the same way sarcoma growing in the plasma of immune rats has been transmitted to normal animals. The plasma from immune animals does not seem, then, in this short time, to influence deleteriously the subsequent growth of sarcoma tissue when this is inoculated into animals.

SUBCULTURES

ARSENIC IN SYPHILIS

A. HERZFELD, M.D.
NEW YORK

That mercury does not cure syphilis in all cases has been observed for many centuries. Christian Friedrich Harles[1] mentions the fact that Fallopius and Libavius used arsenic in the treatment of syphilis. F. Hoffmann[2] in the middle of the eighteenth century used the flores auri pigmenti diaphoretici, a sulphid of arsenic, satisfactorily in the treatment of "lues venerea inveterata," in cases in which mercury proved of no avail, and in cases in which ptyalism and mercurial poisoning were produced. Hoffmann asserts that he obtained excellent results by the internal administration of arsenic in the treatment of indolent syphilitic lymph-nodes, cachexia syphilitica, and in syphilitic periostitis. C. Ziegenbuchler[3] used arsenic internally in the treatment of syphilitic arthritis with success. Horn[4] and Renner[5] treated old inveterate syphilitic lesions successfully with white arsenic. The use of arsenic in the treatment of syphilis is, therefore, by no means a modern invention.

Let us now see how salvarsan has fulfilled Ehrlich's ideas in the treatment of syphilis. Was the early enthusiasm which followed the use of this preparation an enthusiasm largely due to the fact that a new remedy was announced by one of the greater leaders in medicine, justified? Are the results following the use of salvarsan comparable to those which we expect from the administration of quinin in malaria? The answer to the question has been furnished by Neisser at the medical congress at Koenigsberg, Sept. 20, 1910. Neisser, a most profound observer, whose use of salvarsan has been very extensive, recommends a primary injection of salvarsan and repeats this injection after from three to six weeks; in nearly all cases he subjects the patient during this three or six weeks' intermission to a regular treatment with mercury in the form of injections with gray oil. This procedure is to be repeated until a permanent negative Wassermann reaction is obtained.

Despite the reported apparently brilliant results that have been obtained with the injection of salvarsan recurrences are being reported with greater and greater frequency, forcing us to the conclusion that a *sterilisatio magna* in Ehrlich's sense is in many cases not possible. The use of mercury and potassium iodid and in some cases quinin, in the treatment of syphilis cannot in my opinion be eliminated at the present time, even though I believe that potassium iodid will not cure syphilis, but mercury has cured in many cases, which some of the salvarsan enthusiasts seem to have forgotten entirely. The enthusiasm reached such a point that it was predicted that such metasyphilitic diseases as tabes and general paresis were a thing of the past.

In the treatment of syphilis, there are undoubtedly many factors which Ehrlich's inspiring researches do not fully explain. Why, for instance, do cases occur in which mercury brings about a rapid disappearance of all syphilitic manifestations, although the Wassermann reaction remains positive? Why does an early tabes and progressive paralysis sometimes occur in certain patients who have been subjected to a thorough course of treatment? Why does a positive Wassermann reaction persist years after the primary infection in some patients who have not been treated with mercury, and who nevertheless do not acquire tabes or paresis? On the other hand, it is well known that there are cases, an appreciable number of them, which do badly under any form of chemotherapy.

The most important field for the use of the Ehrlich-Hata preparation is in the acute stages of syphilis, in which forms this remedy has proved of paramount value. Even if it does nothing more than to heal the primary lesion as rapidly as it does, and thereby prevent a further invasion of the system, and close an avenue of infection to others, it has accomplished a great deal. In the treatment of the chronic inveterate forms of syphilis its use has, as yet, not been sufficiently extensive to enable us to judge of its powers.

In the treatment of some of the diseases of the blood-forming organs, severe anemia, pernicious anemia, pseudoleukemia and lymphatic swellings of various origin, including glandular tuberculosis, its use has not been attended with success. In these maladies the inorganic preparations of arsenic act more rapidly and are more lastingly efficient than the organic preparations, a response similar to those noted after the administration of the organic and inorganic iron preparations in the treatment of the anemias and of chlorosis.

In these maladies and in cases of inveterate syphilis, which responded no longer to mercury, I have used successfully a solution of arsenic, which I described[6] in 1909. The solution consists of 1 gm. arsenic trioxid and 2.25 c.c. normal soda solution in 100 c.c. of distilled water, representing a 1 per cent. solution of sodium arsenite, a solution which is very slightly alkaline. Its subcutaneous injection does not cause more inconvenience than an injection of morphin; its intramuscular injection is painless. Lately I have used the intramuscular method (glutei) exclusively. I have given these injections hundreds of times and I have never seen even the slightest tendency to suppuration. The skin before injection is disinfected with an alcoholic solution of iodin and potassium iodid, and the site of injection is sealed with a mixture of this iodin solution with tincture of benzoin in the proportion of 1 to 4, a procedure which I have have also reported elsewhere.[7]

I shall briefly report two cases of syphilis in which the results of treatment with my arsenic solution were exceedingly satisfactory.

In a woman, aged 32, in whom the secondary lesions were not affected in the least by injection of mercury for a period of six months, injections of my solution of arsenic brought about a rapid disappearance of all syphilitic lesions after fourteen injections.[8]

A young woman, aged 24, in whom syphilitic manifestations kept appearing for a period of five years after the initial lesion, despite active mercurial treatment, was completely cured after twenty-four injections of my arsenic solution. Repeated Wassermann reactions in this case were entirely negative.

I wish to say a few words regarding the use of certain preparations of arsenic in the treatment of syphilis, which, because of convenience in administration, are extensively used in this country. The sodium salt of cacodylic acid, the sodium dimethylarsenate, for instance, is supposed to possess the advantage of being less poisonous than the other arsenic compounds, and has therefore been recommended especially by the French authors. Fraser of Glasgow has shown, however, that the non-toxicity of the cacodylates is due to the fact that they are not split up within the body, and pass out in the urine unchanged. Schmiedeberg asserts that only a very minute quantity of the cacodylic acid is set free in the body and that this is excreted by the lungs and causes a disgusting garlic odor to the breath. I mention these facts merely because these preparations have been recommended lately in The Journal by Murphy and Caffrey.[9] As regards enesol, a French preparation of arsenic that has been recently much in vogue, mainly because of the simplicity of its administration, Bachem[10] asserts that this patented arsenic and mercury mixture is unreliable. The tablets of sodium arsenate on the market for hypodermic use vary in their chemical reaction. Some I found alkaline, some acid; their age is unknown, and their dosage not reliable.

WEAK MEDICAL SCHOOLS AS NURSERIES OF MEDICAL GENIUS

HENRY S. PRITCHETT
President of the Carnegie Foundation for the Advancement of Teaching
NEW YORK

The "Report on Medical Education in the United States and Canada," prepared under the direction of the Carnegie Foundation by Mr. Abraham Flexner, was issued in June and has received in one way or another the criticism of nearly all medical journals and medical associations. Those who have represented the Carnegie Foundation in this matter have sought to examine such criticisms and comments in a fair and reasonable spirit. They have felt pleased that the essential facts stated in the report have received no serious contradiction. They have endeavored, on the other hand, to profit in the further study of medical education by the comments made and the criticisms offered.

It is to be remembered that this report was not a mere criticism of existing conditions. It aimed to point out accurately and frankly the present status of medical education; but it did much more than this. It attempted a thorough-going study of the medical curriculum and it suggested certain broad lines on which the medical curriculum might fairly be expected to develop in the immediate future.

In seeking to serve both of these ends the report inevitably bore with some sharpness on a large proportion of existing medical schools and particularly on those schools which are commercial in their organization; and by "commercial" it was not meant that those who carry on such schools always derive from them much remuneration in the way of money. A commercial school, in the sense in which the term was used in this report, is a school conducted and managed in the interest of the men who control it; these men expect to receive from it some form of reward, either direct or indirect. The report made clear the fact that all such schools are to-day offering a form of preparation for medicine which falls far below the grade of efficiency which the people of every state in the Union have a right to demand. It was to be expected that the sharpest replies to the report should come from those institutions whose organization and plan of control run squarely against the principles it advocates. In particular, the commercial medical establishments have in one form or another replied to the facts laid bare in the report, and the deductions made from these facts, with arguments of varying sincerity and relevancy.

The argument which was most commonly put forth at first was the time-worn plea for the poor boy. The poor school, it was argued, existed for the poor boy. This argument, however, had been so thoroughly anticipated in the report itself and was so clearly not in favor of the poor boy, but in favor of the poor medical school, that it has been practically given up by those who first resorted to its use. In its stead there has been presented in one quarter or another an interesting and singular plea. It is true, say those who put forward this second argument, that a large proportion of the men admitted into the weak medical schools are utterly unprepared; it is true that many of those graduated from such schools ought never to be admitted to practice. Nevertheless, they assert, every now and again in this army of the unfit and the unprepared the school finds some one whom it develops into a great physician or a great investigator—a genius in medical science—and it is worth while, say the advocates of such schools, to keep alive even the weakest medical schools for the sake of the occasional great men whom they may breed.

The most interesting effort to maintain this position which has come under my eye, and one which has been reprinted in many quarters, appeared in an editorial article in *American Medicine* in October. The attention which has been given to it arises largely out of the fact that the author undertakes to rebuke Mr. Abraham Flexner in his criticism of the University of Louisville Medical School on the ground that his distinguished brother, Dr. Simon Flexner, is a graduate of that institution. The article carries with it something of the force of an *argumentum ad hominem.*

The tenor of the article may be judged from the following extract:

> What we have stated about Dr. Simon Flexner—facts that no one will gainsay—show conclusively, though perhaps inefficiently, his great usefulness both to his confrères in medicine and to humanity in general. Measured by his scientific stature, his contributions to medicine and his achievements, Dr. Simon Flexner in the light of his brother's dicta concerning medical colleges and their capacities for developing useful physicians, should be a graduate of some one of the large and best-equipped universities. But alas, fate ordained differently, and, according to the last edition of the *American Medical Directory,* Dr. Simon Flexner, the saver of babies' lives, director of one of the world's most famous and most important scientific institutions, a splendid scholar, one of the world's greatest scientists, a man who already has achieved wonders in his chosen field, and one who, if his life is spared, will probably be responsible for the conquest of several of humanity's most fatal maladies, suffered the frightful handicap of equipping himself for his life's work at the University of Louisville Medical Department. . . .
>
> We realize that there are other phases of the question and a single case like this offers no real opportunities for comparisons or conclusions. But we still think it carries a valuable lesson and proves our contention that after all the personal equation is the important factor. We need all the Simon Flexners we can get, and a school that can help one such man in each decade to embark on a career so useful to his fellows and all mankind, has justified its existence, Brother Abraham notwithstanding.

It would be difficult to misrepresent the facts in the case more completely than they have been misrepresented here. The scientific work which Dr. Simon Flexner has done has all been in relation to the subjects of pathology and bacteriology. In the year 1889, when the University

ARSENIC IN SYPHILIS

A. HERZFELD, M.D.
NEW YORK

That mercury does not cure syphilis in all cases has been observed for many centuries. Christian Friedrich Harles[1] mentions the fact that Fallopius and Libavius used arsenic in the treatment of syphilis. F. Hoffmann[2] in the middle of the eighteenth century used the flores auri pigmenti diaphoretici, a sulphid of arsenic, satisfactorily in the treatment of "lues venerea inveterata," in cases in which mercury proved of no avail, and in cases in which ptyalism and mercurial poisoning were produced. Hoffmann asserts that he obtained excellent results by the internal administration of arsenic in the treatment of indolent syphilitic lymph-nodes, cachexia syphilitica, and in syphilitic periostitis. C. Ziegenbuchler[3] used arsenic internally in the treatment of syphilitic arthritis with success. Horn[4] and Renner[5] treated old inveterate syphilitic lesions successfully with white arsenic. The use of arsenic in the treatment of syphilis is, therefore, by no means a modern invention.

Let us now see how salvarsan has fulfilled Ehrlich's ideas in the treatment of syphilis. Was the early enthusiasm which followed the use of this preparation an enthusiasm largely due to the fact that a new remedy was announced by one of the greater leaders in medicine, justified? Are the results following the use of salvarsan comparable to those which we expect from the administration of quinin in malaria? The answer to the question has been furnished by Neisser at the medical congress at Koenigsberg, Sept. 20, 1910. Neisser, a most profound observer, whose use of salvarsan has been very extensive, recommends a primary injection of salvarsan and repeats this injection after from three to six weeks; in nearly all cases he subjects the patient during this three or six weeks' intermission to a regular treatment with mercury in the form of injections with gray oil. This procedure is to be repeated until a permanent negative Wassermann reaction is obtained.

Despite the reported apparently brilliant results that have been obtained with the injection of salvarsan recurrences are being reported with greater and greater frequency, forcing us to the conclusion that a *sterilisatio magna* in Ehrlich's sense is in many cases not possible. The use of mercury and potassium iodid and in some cases quinin, in the treatment of syphilis cannot in my opinion be eliminated at the present time, even though I believe that potassium iodid will not cure syphilis, but mercury has cured in many cases, which some of the salvarsan enthusiasts seem to have forgotten entirely. The enthusiasm reached such a point that it was predicted that such metasyphilitic diseases as tabes and general paresis were a thing of the past.

In the treatment of syphilis, there are undoubtedly many factors which Ehrlich's inspiring researches do not fully explain. Why, for instance, do cases occur in which mercury brings about a rapid disappearance of all syphilitic manifestations, although the Wassermann reaction remains positive? Why does an early tabes and progressive paralysis sometimes occur in certain patients who have been subjected to a thorough course of treatment? Why does a positive Wassermann reaction persist years after the primary infection in some patients who have not been treated with mercury, and who nevertheless do not acquire tabes or paresis? On the other hand, it is well known that there are cases, an appreciable number of them, which do badly under any form of chemotherapy.

The most important field for the use of the Ehrlich-Hata preparation is in the acute stages of syphilis, in which forms this remedy has proved of paramount value. Even if it does nothing more than to heal the primary lesion as rapidly as it does, and thereby prevent a further invasion of the system, and close an avenue of infection to others, it has accomplished a great deal. In the treatment of the chronic inveterate forms of syphilis its use has, as yet, not been sufficiently extensive to enable us to judge of its powers.

In the treatment of some of the diseases of the blood-forming organs, severe anemia, pernicious anemia, pseudoleukemia and lymphatic swellings of various origin, including glandular tuberculosis, its use has not been attended with success. In these maladies the inorganic preparations of arsenic act more rapidly and are more lastingly efficient than the organic preparations, a response similar to those noted after the administration of the organic and inorganic iron preparations in the treatment of the anemias and of chlorosis.

In these maladies and in cases of inveterate syphilis, which responded no longer to mercury, I have used successfully a solution of arsenic, which I described[6] in 1909. The solution consists of 1 gm. arsenic trioxid and 2.25 c.c. normal soda solution in 100 c.c. of distilled water, representing a 1 per cent. solution of sodium arsenite, a solution which is very slightly alkaline. Its subcutaneous injection does not cause more inconvenience than an injection of morphin; its intramuscular injection is painless. Lately I have used the intramuscular method (glutei) exclusively. I have given these injections hundreds of times and I have never seen even the slightest tendency to suppuration. The skin before injection is disinfected with an alcoholic solution of iodin and potassium iodid, and the site of injection is sealed with a mixture of this iodin solution with tincture of benzoin in the proportion of 1 to 4, a procedure which I have have also reported elsewhere.[7]

I shall briefly report two cases of syphilis in which the results of treatment with my arsenic solution were exceedingly satisfactory.

In a woman, aged 32, in whom the secondary lesions were not affected in the least by injection of mercury for a period of six months, injections of my solution of arsenic brought about a rapid disappearance of all syphilitic lesions after fourteen injections.[8]

A young woman, aged 24, in whom syphilitic manifestations kept appearing for a period of five years after the initial lesion, despite active mercurial treatment, was completely cured after twenty-four injections of my arsenic solution. Repeated Wassermann reactions in this case were entirely negative.

I wish to say a few words regarding the use of certain preparations of arsenic in the treatment of syphilis, which, because of convenience in administration, are extensively used in this country. The sodium salt of cacodylic acid, the sodium dimethylarsenate, for instance, is supposed to possess the advantage of being less poisonous than the other arsenic compounds, and has therefore been recommended especially by the French authors. Fraser of Glasgow has shown, however, that the non-toxicity of the cacodylates is due to the fact that they are not split up within the body, and pass out in the urine unchanged. Schmiedeberg asserts that only a very minute quantity of the cacodylic acid is set free in the body and that this is excreted by the lungs and causes a disgusting garlic odor to the breath. I mention these facts merely because these preparations have been recommended lately in The Journal by Murphy and Caffrey.[9] As regards enesol, a French preparation of arsenic that has been recently much in vogue, mainly because of the simplicity of its administration, Bachem[10] asserts that this patented arsenic and mercury mixture is unreliable. The tablets of sodium arsenate on the market for hypodermic use vary in their chemical reaction. Some I found alkaline, some acid; their age is unknown, and their dosage not reliable.

WEAK MEDICAL SCHOOLS AS NURSERIES OF MEDICAL GENIUS

HENRY S. PRITCHETT
President of the Carnegie Foundation for the Advancement of Teaching
NEW YORK

The "Report on Medical Education in the United States and Canada," prepared under the direction of the Carnegie Foundation by Mr. Abraham Flexner, was issued in June and has received in one way or another the criticism of nearly all medical journals and medical associations. Those who have represented the Carnegie Foundation in this matter have sought to examine such criticisms and comments in a fair and reasonable spirit. They have felt pleased that the essential facts stated in the report have received no serious contradiction. They have endeavored, on the other hand, to profit in the further study of medical education by the comments made and the criticisms offered.

It is to be remembered that this report was not a mere criticism of existing conditions. It aimed to point out accurately and frankly the present status of medical education; but it did much more than this. It attempted a thorough-going study of the medical curriculum and it suggested certain broad lines on which the medical curriculum might fairly be expected to develop in the immediate future.

In seeking to serve both of these ends the report inevitably bore with some sharpness on a large proportion of existing medical schools and particularly on those schools which are commercial in their organization; and by "commercial" it was not meant that those who carry on such schools always derive from them much remuneration in the way of money. A commercial school, in the sense in which the term was used in this report, is a school conducted and managed in the interest of the men who control it; these men expect to receive from it some form of reward, either direct or indirect. The report made clear the fact that all such schools are to-day offering a form of preparation for medicine which falls far below the grade of efficiency which the people of every state in the Union have a right to demand. It was to be expected that the sharpest replies to the report should come from those institutions whose organization and plan of control run squarely against the principles it advocates. In particular, the commercial medical establishments have in one form or another replied to the facts laid bare in the report, and the deductions made from these facts, with arguments of varying sincerity and relevancy.

The argument which was most commonly put forth at first was the time-worn plea for the poor boy. The poor school, it was argued, existed for the poor boy. This argument, however, had been so thoroughly anticipated in the report itself and was so clearly not in favor of the poor boy, but in favor of the poor medical school, that it has been practically given up by those who first resorted to its use. In its stead there has been presented in one quarter or another an interesting and singular plea. It is true, say those who put forward this second argument, that a large proportion of the men admitted into the weak medical schools are utterly unprepared; it is true that many of those graduated from such schools ought never to be admitted to practice. Nevertheless, they assert, every now and again in this army of the unfit and the unprepared the school finds some one whom it develops into a great physician or a great investigator—a genius in medical science—and it is worth while, say the advocates of such schools, to keep alive even the weakest medical schools for the sake of the occasional great men whom they may breed.

The most interesting effort to maintain this position which has come under my eye, and one which has been reprinted in many quarters, appeared in an editorial article in *American Medicine* in October. The attention which has been given to it arises largely out of the fact that the author undertakes to rebuke Mr. Abraham Flexner in his criticism of the University of Louisville Medical School on the ground that his distinguished brother, Dr. Simon Flexner, is a graduate of that institution. The article carries with it something of the force of an *argumentum ad hominem.*

The tenor of the article may be judged from the following extract:

> What we have stated about Dr. Simon Flexner—facts that no one will gainsay—show conclusively, though perhaps inefficiently, his great usefulness both to his confrères in medicine and to humanity in general. Measured by his scientific stature, his contributions to medicine and his achievements, Dr. Simon Flexner in the light of his brother's dicta concerning medical colleges and their capacities for developing useful physicians, should be a graduate of some one of the large and best-equipped universities. But alas, fate ordained differently, and, according to the last edition of the *American Medical Directory,* Dr. Simon Flexner, the saver of babies' lives, director of one of the world's most famous and most important scientific institutions, a splendid scholar, one of the world's greatest scientists, a man who already has achieved wonders in his chosen field, and one who, if his life is spared, will probably be responsible for the conquest of several of humanity's most fatal maladies, suffered the frightful handicap of equipping himself for his life's work at the University of Louisville Medical Department. . . .
>
> We realize that there are other phases of the question and a single case like this offers no real opportunities for comparisons or conclusions. But we still think it carries a valuable lesson and proves our contention that after all the personal equation is the important factor. We need all the Simon Flexners we can get, and a school that can help one such man in each decade to embark on a career so useful to his fellows and all mankind, has justified its existence, Brother Abraham notwithstanding.

It would be difficult to misrepresent the facts in the case more completely than they have been misrepresented here. The scientific work which Dr. Simon Flexner has done has all been in relation to the subjects of pathology and bacteriology. In the year 1889, when the University of Louisville conferred on him the M.D. degree, the medical school of the University of Louisville had no laboratory for either pathology or bacteriology. Bacteriology was not even taught, and pathology, if taught at all, was taught only in a few lectures given by a practicing physician. The fact is that Dr. Simon Flexner got his real training by ten years of work at the Johns Hopkins University, and these the years which were the most fruitful in its history—the years when Professor Welch, starting with a few chosen pupils, brought up that group of men whose labors have gone so far to revolutionize American medical education in the brief period of two decades. It is difficult to believe that the writer of the paragraphs quoted did not know that Simon Flexner obtained his scientific training, not at the Louisville medical school, but at the Johns Hopkins University.

[9] Murphy, John B.: The Arsenical Treatment of Syphilis, The Journal A. M. A., Sept. 24, 1910, p. 1113. Caffrey, A. J.: Sodium Cacodylate in Syphilis, ibid., Dec. 24, 1910, p. 2211.

[10] Bachem: Berliner klin., October, 1910.

While this disposes of the *argumentum ad hominem*, it does not affect the underlying question. The assertion that weak institutions deserve to exist on the ground of the few great men who have come up through them is one constantly made. The argument is, however, fallacious. It is not true that a vast horde of unprepared and ill-trained physicians must be turned out on a helpless public in order to obtain an occasional medical genius. The medical genius, when he comes, will in no way be shut out by the fact that the medical school is on decent standards. On the contrary, the very presence of a group of able, distinguished professors will stimulate such men to emulate their example and to live up to their ideals. It will always happen that a few of the best men will come up from the weaker schools; but the fact that strong men can survive a handicap is a strange reason for maintaining handicaps which injure even the strong man and wreck very many others. The medical genius of thirty years ago had no choice; he had to go to a poor school, for no other kind existed. To-day he has a good many alternatives. It is to his interest, genius though he be, that he be compelled to prepare adequately for his medical career and to get a good medical training on this sound basis. Such a policy, of priceless importance to the supposed medical genius, is absolutely indispensable to the man of mediocre ability, and to the public which is at his mercy. The exceptions are apparent rather than real. How much more effective would even the genius have been, if he had not been handicapped by defects of training! Facts showing that a man of high purpose and extraordinary ability may find his way, even under adverse and unfavorable conditions, in no wise furnish an argument, or even an excuse, for making the conditions of education weak and ineffective and for imposing on the public a body of ill-prepared practitioners.

In all the discussion concerning the poor boy and the medical genius it is well that the public and the medical profession should not be drawn away from the fundamental reasons advanced in this report to show that commercial schools are to-day hindering, not helping, the cause of medicine. These reasons, briefly restated, are the following:

1. Such schools are essentially proprietary institutions. They are schools managed by physicians who are to profit both directly and indirectly by the enterprise itself. It is true that some of these are nominally branches of universities, but this arrangement is fictitious. This situation has been proved by long experience to be one under which right educational conditions are impossible. A college or an engineering school run under similar conditions would also become frankly commercial.

2. Schools so run must depend on fees. This means inevitably the recruiting of a large student body from the unprepared and the unfit. In most schools of this character advertising is freely resorted to. To secure the requisite number of men, standards, both of preliminary education and of technical training, must necessarily be kept so low that the large body can be admitted. This results in putting the instruction itself on a low plane.

3. Adequate endowment for medical education can never be obtained so long as the exploitation of medical education for commercial purposes is wide-spread. It is a striking fact in educational conditions in America to-day that medical education has received very meager support. Particularly is this true when it is remembered that the service which the physician renders to the average man of means is the most direct and personal service which any member of society can offer. No other man has so good an opportunity to present the cause in which he is interested as the family physician. Under such conditions the poverty of endowment of American medical education is a standing reproach to American men of medicine. It is due, as everyone knows, to the fact that the average business man understands that medical education has been hitherto a perquisite of the medical practitioner, and so long as that relation remains no large endowment of medicine can be had. Only when the medical school is managed by a board of men not directly concerned in its profits, whether they be in the form of fees or of increased practice, will it stand in the eyes of givers in the same light as other schools.

4. Finally, the continuance of such schools under their present conditions is a direct neglect of the rights of the students themselves and of the public, and this for the reason that so long as the conditions which have been described hold, these schools furnish a sort of education far inferior to that which they ought to give and far inferior as well to that which the public has a right to expect of those who are to practice on it. Such schools are practically in the situation which a commercial house would occupy if it sold its patrons old and antiquated machinery, presuming on their ignorance.

It is interesting to see with what success some medical sects, for example, the osteopaths, have learned from the history of medical education to ignore the claims of the public in their own interest. A brief and meager education is justified on the ground that the "science" is not as yet so comprehensive as "regular medicine" in its scope; but the osteopath, once graduated, is very vague as to just what he should or should not attempt to relieve by osteopathic methods; in consequence, he will at least try to cure everything! The dean of an osteopathic school in California admitted that his students are taught to treat even such affections as gonorrhea and syphilis by "osteopathic" methods. In a number of states the osteopaths are thus conducting schools which, while nominally osteopathic establishments, are really, by the aid of feeble departments of anatomy, pathology, and physiology, turned into the weakest of ordinary medical schools. On the plea that they are training a physician of limited range, they get from the state a concession enabling them to give the degree of D.O. in three years, instead of four; the graduates, though so poorly trained that under any other name they would not be admitted to practice at all, at once spread themselves over the entire field of illness, disease, and accident. But in carrying out this program, the osteopaths have done nothing other than to imitate the example of the weak medical school which goes on furnishing to those who attend it a form of education enormously behind the requirements of our day and our time, while giving to the public the impression that it is offering facilities of an adequate and satisfactory sort.

One cannot study even the weakest and most unnecessary of these schools without realizing that not infrequently an admirable quality of devotion is to be found in them. The difficulty is that such devotion is mingled with a very large leaven of commercial interest; and in many cases the devotion is offered in a cause which cannot be approved. The betterment of medical education to a stage commensurate with the present status of medical knowledge is a task which will require the unselfish service, first of all, of the members of the medical profession. It is difficult to see how that service can be rendered until the members of this profession themselves are willing to acknowledge that, whatever may have been true of the past, the time has now come when the commercial medical school should disappear and in its place there should stand a school which, however simple and humble it may be, shall be conducted in accordance with an ideal which divorces the teaching of the doctor or surgeon from the question of securing practice and which unites both science and practice for the benefit of those students who are competent to receive the instruction.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

ANTIDYSENTERIC SERUM.—Farbwerke vorm. Meister, Lucius & Bruening, Hoechst a. M., Germany (Victor Koechl & Co., New York).

Antidysenteric Serum.—The blood serum of horses immunized against the Shiga bacillus. Recommended in dysentery and summer diarrhea where the bacillus of Shiga is an etiologic factor. Marketed in bottles containing respectively 10 and 20 Cc.

ANTIPNEUMOCOCCUS SERUM.—Farbwerke vorm. Meister, Lucius & Bruening, Hoechst a. M., Germany (Victor Koechl & Co., New York).

Antipneumococcus Serum, stated to be prepared from highly virulent original cultures derived from human pneumococcus affections. Marketed in bottles containing 10 and 20 Cc., and also in powder form in vials containing 1 Gm. each. The dry serum is intended principally for the local treatment of ulcus serpens.

ARHOVIN.—Arhovin is stated to be a solution of diphenylamine and thymolbenzoate in ethyl benzoate, the three constituents being in molecular proportions.

Arhovin is a yellowish liquid of aromatic odor and feebly cool-burning taste, on account of which it is supplied, for oral administration, in capsule form. It is almost insoluble in water, but readily soluble in alcohol, ether, chloroform and fatty oils.

Actions and Uses.—Arhovin is rapidly absorbed and excreted, being present in the urine fifteen minutes after ingestion. It has an antiseptic action on the urine and, it is claimed, it renders the mucosa of the genito-urinary tract unfavorable for germ growth. It is said to clear up cloudy urine and make it normally acid.

Arhovin is said to be useful in the treatment of urethritis, prostatitis, cystitis, and pyelitis, as an adjunct to local treatment. It is said to be useful for external application in place of silver salts.

Dosage.—By mouth, 0.25 (4 minims), in capsule, 1 or 2 capsules three to six times daily. For urethral injections: 3 to 5 per cent. solutions in olive oil or liquid petrolatum; 15 c.c. two to four times daily.

Manufactured by Dr. Arthur Horowitz, Berlin, Germany (Schering & Glatz, New York). U. S. trademark No. 58,756. Not patented.

Arhovin Capsules.—Each capsule is said to contain 0.25 Gm. (4 minims) of arhovin.

MAGNESIUM PEROXIDE.—Magnesium Peroxidatum.—Magnesium superoxide. Magnesium dioxide.—Magnesium peroxide is a mixture consisting essentially of magnesium peroxide and magnesium oxide with water of hydration, containing not less than 15 per cent. of magnesium peroxide (MgO_2).

Magnesium peroxide is a white powder. It is practically insoluble in water, but by such contact is gradually decomposed into hydrogen peroxide and magnesium hydroxide, the hydrogen peroxide being further decomposed by the alkaline magnesium hydroxide, with liberation of oxygen. It is decomposed by dilute acids with formation of a solution containing hydrogen peroxide.

If about 1 Gm. of magnesium peroxide be dissolved in a mixture of 10 Cc. dilute sulphuric acid and 90 Cc. water a solution results, 1 Cc. of which shaken with 5 Cc. ether and 1 drop of a 1/100 chromic acid solution should produce a blue color in the ether.

If about 0.2 Gm. magnesium peroxide be boiled with 10 Cc. water, then cooled and filtered, the filtrate should be but faintly alkaline; and 5 Cc. of this filtrate on evaporation should leave only a trace of residue.

If about 1 Gm. magnesium peroxide be dissolved in 25 Cc. dilute nitric acid and 2 Cc. tenth-normal silver nitrate added to the solution and the resulting precipitate filtered off, the further addition of a few drops of silver nitrate solution to the filtrate should not produce a turbidity.

If about 1 Gm. magnesium peroxide be exposed to the full heat of a Bunsen flame for five minutes, then dissolved in 25 Cc. dilute hydrochloric acid and the solution made up to 100 Cc., a solution will result which will conform to the following tests:

10 Cc. of the solution saturated with hydrogen sulphid should yield no precipitate, nor become colored.

10 Cc. of the solution, to which 10 Cc. ammonium chlorid solution and ammonium hydroxid in excess have been added, should yield not more than a turbidity on the addition of ammonium carbonate.

10 Cc. of the solution should not immediately give a blue color on the addition of a drop of potassium ferrocyanid solution.

If 0.2 to 0.3 Gm. magnesium peroxide, weighed into a flask, be dissolved with 20 Cc. dilute sulphuric acid, the solution diluted with 50 Cc. water, the titration of this solution with tenth-normal potassium permanganate should indicate the presence of not less than 15 per cent. magnesium peroxide, MgO_2.

Actions and Uses.—Magnesium peroxide, due to its property of yielding oxygen is said to be of value as a gastric and intestinal antiseptic. It has been recommended in chlorosis, anemia, gout and rheumatism. It is also used as a constituent of dentifrices.

Dosage.—0.25 to 0.50 gm. (4 to 7 grains) two or three times daily.

Therapeutics

DRUGS ACTING ON THE CIRCULATION

STROPHANTHUS

Description.—*Strophanthus hispidus* (genitive strophanthi, Latin masculine noun, second declension) derives its name from the Greek στροφή a turn or a twist, and ἄνθος a flower, from the twisted, thread-like segments of the corolla, and *hispidus*, Latin meaning hairy, the seeds being covered with hairs. Strophanthus is a woody climber in the forests of tropical Asia and Africa. The United States Pharmacopeia recognizes as official the seeds of *Strophanthus hispidus* De Candolle.

The natives of Africa, especially along the Zanzibar coast, express from the seeds of this plant an oily juice which they smear on their arrow-heads. This poison is variously known as the Kombé poison, or the Inée or Onaye poison, or the Wanika poison, or the Pahouins poison, depending on the region of Africa in which this poison is used.

The seeds of strophanthus contain from 1 to 4 per cent. of a glucosid extracted with alcohol and hydrochloric acid, and an acid called by Culbreth kombic acid. This glucosid is probably similar in action to the ouabain, the active principle obtained from the seeds of *Strophanthus glaber*.

The Kombé arrow-poison, named strophanthus by Sir John Kirk, was first examined in 1862 by Professor Sharpey, but the action of strophanthus was first presented to the profession by Professor T. R. Fraser, of Edinburgh, in 1870. Professor Fraser obtained from the seeds a bitter, white, imperfectly crystallin principle, *strophanthin*, which is a glucosid changed by sulphuric acid into glucose and crystallin strophanthidin. Strophanthin is more poisonous than strychnin, atropin and even hydrocyanic acid.

Strophanthus has not been used so much as its physiologic action authorizes because the best liquid preparation of it, the tincture, was supposed to vary so greatly in strength and efficiency as to render the use of the drug in this form uncertain. The U. S. P. tincture, if made by a reliable firm, has been shown by repeated examinations to be of good and efficient strength, although like all tinctures of crude drugs, the strength varies, though not so widely as does the tincture of digitalis. The mistake is often made of adding tincture of strophanthus to some watery solution. Watery menstrua have been shown to diminish the efficiency and to injure the activity of tincture of strophanthus. Therefore, the tincture of strophanthus should be ordered alone or, if deemed advisable, in combination with some other tincture.

Local Action.—Strophanthus has no action on the unbroken skin. If the volatile oil contained in the seeds is entirely removed before the preparations are made, strophanthus has but slight irritant action on the mucous membranes, but large doses of most preparations may cause nausea and vomiting and perhaps diarrhea. In small doses the slight irritation which is caused will act as a stomachic or bitter tonic.

Systemic Action.—Although strophanthus has been estimated as sixty times as toxic as digitalis, leaving out for a moment this toxic power, it may be epigrammatically described *from the therapeutic standpoint* as acting "just like digitalis, only less so." In other words, it is less slow of absorption and therefore more rapid to act; it is less likely to cause vomiting; it slows the heart less, increases its contractions less, and causes less contraction of the blood-vessels, especially those of the splanch[illegible] area and the coronaries; and it is less likely to [illegible]e cumulative action. The active constituents of this [illegible]g are rapidly absorbed, and also rapidly excreted, hence if the doses are not too frequently repeated, as just stated, there is no danger of cumulative effect. Its action may be noticed in half an hour after it is administered and the effect will last for several hours.

The primary action of this drug, like digitalis, is on the *circulatory system*. The heart muscle is as strongly stimulated as by digitalis. The heart is slowed and the diastole prolonged probably by the action on the peripheral endings of the pneumogastric nerves in the heart.

It has been generally believed that strophanthus does not cause much arterial contraction and therefore does not much raise the systemic blood-pressure. Pharmacologic experiments, however, seem to show that it does raise the blood-pressure by causing arterial contraction. Clinically, however, in a dose sufficient to act on the heart it does not raise the blood-pressure as does the same efficient doses of digitalis. Even when the blood-pressure is raised by it, it has seemed not to raise the pulmonary pressure. Hence strophanthus can be used in arteriosclerosis when digitalis is contra-indicated.

In ordinary dosage, strophanthus has but slight, if any, effect on the *nervous system*, but if any effect is produced on the brain and medulla it seems to be that of a slight sedative. Whether such quieting effect is due to an improved circulation or to a possible sedative effect on the thyroid gland, which if excited is the cause of cerebral excitation and nervousness, cannot be decided. From this sedative effect on the higher nerve centers, which under certain excited conditions is marked, nervous muscular irritability is diminished and strophanthus thus becomes a mild antipyretic.

Locally on the eye strophanthus in doses of 1/1000 grain will produce anesthesia of the conjunctiva, contraction of the pupil, and increased intra-ocular tension, but it later causes severe irritation.

In therapeutic doses, strophanthus has no action on the *muscular system*, but in toxic doses is a direct paralyzant of the voluntary muscles acting either on the endings of the motor nerves, or on the muscle itself.

The *glands* of the body are not affected except as by the general improved circulation, except that profuse perspiration may be diminished, and there is strong clinical proof that in hypersecretion of the thyroid as occurs in Graves' disease the secretion of this gland is diminished.

It is a moot question as to whether this drug has *diuretic* properties other than that caused by the improved circulation, but it does cause diuresis in some cases in which digitalis has seemed to fail. It does not cause contraction of the renal blood-vessels, but very probably is slightly stimulant to the kidney secreting cells. This drug is rapidly eliminated and there is no danger of cumulative action if the dose is not too rapidly repeated.

Action of a Therapeutic Dose, or the Primary Physiologic Action.—Good therapeutic action of strophanthus is shown by a slowed pulse with slightly increased arterial tension, stronger and regular action of the heart, diminished nervous irritability, and an increased amount of urine. The *toxic action* of strophanthus is shown by disturbed circulation, as occurs with a toxic dose of digitalis, and great muscular weakness.

The treatment of strophanthus poisoning is similar to that of digitalis poisoning.

Therapy.—The indications for preferring and using strophanthus instead of digitalis are:

First, when there is an indication for a cardiac tonic and digitalis produces nausea, vomiting, and too great increase of blood-pressure.

Second, when a cardiac tonic is indicated and the blood-pressure is already high.

Third, when a rapidly acting cardiac tonic is indicated.

Fourth, when there is more nervous irritability and weakening of the heart than actual muscular debility or incompetency.

Fifth, children are very susceptible to the action of digitalis, and hence strophanthus is often a better drug to use when a cardiac tonic is indicated.

Strophanthus can be used for any condition in which digitalis is indicated. It often acts well as a diuretic and in dropsical conditions not due entirely to cardiac incompetency strophanthus acts better than digitalis.

It is of special advantage in chronic nephritis when digitalis is contra-indicated. In the rapid heart and cerebral excitation of Graves' thyroid disease strophanthus is often of marked benefit.

Contra-Indications.—In the conditions in which digitalis is contra-indicated strophanthus should be used with care, but not being a vasoconstrictor in ordinary doses, and not contracting the blood-vessels of the kidneys, and not having cumulative action gives this drug a wider range of use within the realms of conservative therapy, than has the more strongly acting drug, digitalis.

Official Preparations.—Strophanthus is not used as such. *Tinctura Strophanthi:* This is a 10 per cent. tincture; dose 10 drops.

STROPHANTHIN

So much has recently been written of the therapeutic value of strophanthin when injected hypodermatically or intravenously, and, *per contra*, the use of tincture of strophanthus by the mouth has been reported so many times as unsatisfactory, that this active principle is worthy of a brief separate discussion.

The *Strophanthinum* of the Pharmacopeia is a glucosid or mixture of glucosids. It is a white or faintly yellowish crystallin powder, very bitter, and very soluble in water and dilute alcohol. A purer strophanthin may be obtained, but perhaps its activity may not be greater than the mixture of glucosids termed strophanthin of the Pharmacopeia. Ouabain and crystallized strophanthin are identical products and have the same toxic effect, and this substance is perhaps twice as active as is the common strophanthin of the Pharmacopeia. Crystallized strophanthin is a very active poison, claimed to be sixty times as toxic as digitoxin.

By the mouth strophanthin may produce serious poisoning. Tincture of strophanthus probably so soon causes nausea and vomiting that it would be difficult to produce serious poisoning with it; this is, perhaps, not true of strophanthin. On the other hand, its therapeutic effect has been found to be much less when given by the stomach than when given hypodermatically.

The best strophanthin on the market is obtained by a process of extraction, devised by Thoms, from strophanthus gratus, and has a definite melting point and solubility, as determined by Hatcher and Bailey.

Harold C. Bailey (*Journal of Pharmacology and Experimental Therapeutics,* October, 1909) advises that the daily dose of the crystalline strophanthin should not exceed 0.0005 gram, (1/120 of a grain) and that this dose should not be repeated in 24 hours. If crystalline strophanthin is given intramuscularly, it should be dissolved in a 1 to 4,000 saline solution, or for intravenous use in a 1 to 6,000 or 8,000.

The hypodermatic dose is very much less than that by the mouth, and in fact tablets for hypodermic administration are offered, each containing 1/500 of a grain, the dose ranging from 1/500 to 1/100 of a grain. Hatcher (The Journal, March 26, 1910) has several times declared that crystalline strophanthin is twice as toxic as the amorphous strophanthin of the Pharmacopeia.

Strophanthin seems to be especially valuable as a cardiac stimulant when there is weakened heart muscle in chronic myocarditis or in chronic valvular disease, especially if there is coincident nephritis. Hypodermatically, however, strophanthin should probably be reserved for emergencies, although a number of French clinicians give 0.001 gram (1/60 of a grain) of strophanthin intramuscularly or even intravenously, once in 24 hours, for several days, if necessary. On the other hand, once or twice, at 24-hour intervals, is generally sufficient. Administered in this manner, this drug seems quickly to increase the strength of the cardiac contractions, to slow the pulse, and often in cardiac disturbances causes diuresis. However, if the kidneys are damaged, strophanthin may not act as a diuretic unless some other drug is added to the treatment, such as caffein. Although strophanthin is recommended to be used intravenously, it would seem hardly justifiable, except in emergencies. On the other hand, when the heart is failing from cardiac disease or dilatation, and digitalis is contra-indicated or useless, the patient should not be allowed to die without a trial of strophanthin.

Strophanthin has proved successful in relieving almost hopeless pulmonary edema from failure of the right side of the heart.

Symptomatology of Anterior Poliomyelitis

The Board of Health of New York City, in line with many other health boards, has made infantile paralysis a reportable disease. A special form of card has been prepared for recording the cases, and the inspectors have been instructed to pay special attention to securing exact information as to periods of incubation and infectivity. Negative findings may be as important as positive ones. A bulletin has been issued concerning the disease, which gives a clear statement of the symptoms and signs in the light of the late investigations, and also emphasizes the value of the findings in the cerebrospinal fluid. In view of the probability that in the coming warm season many cases of infantile paralysis will occur, this portion of the bulletin may be worth republishing. It says:

"Epidemics of acute poliomyelitis have been noted with increasing frequency in this and other countries. Its infectious nature has long been suspected, and in 1909 was rendered almost certain by the production of the disease in monkeys by inoculation of the emulsified spinal cord of a child that had died of the disease. Studies made at the Rockefeller Institute have made this proof still more conclusive. The virus is contained not only in the spinal cord, but also in other parts of the body, most particularly the nasopharyngeal mucous membrane. This is significant in its relation to isolation and prophylaxis, and suggests a likely source of dissemination.

"Abortive forms without paralysis have been noted and are recognized with difficulty, except during an epidemic. Examination of the cerebrospinal fluid obtained by lumbar puncture is of great assistance in confirming the diagnosis. the distinctive features of the fluid are: clear fluid, absence of bacteria, increased cellular elements (chiefly lymphocytes), moderately increased tension, and definite increase of protein content as shown by Noguchi's test. In a recent case a positive diagnosis was made by lumbar puncture, twenty-four hours before any sign of paralysis appeared. The meningeal and cerebral types of the disease may thus be differentiated from epidemic cerebrospinal meningitis.

"The disease is characterized by a sudden onset with fever, followed, generally, within from twelve hours to three or four days, by general or localized paralysis, almost always of a flaccid type, with reaction of degeneration and early atrophy in the muscles permanently affected. Paralysis is most common in one or both legs, but may occur in any part of the body. Vomiting and convulsions occur frequently at the onset but are not constant symptoms. More significant are restlessness and insomnia which occur early in most cases. Pain and tenderness, usually referred to the joints and muscles, were common in the 1907 epidemic in New York City.

"The period of incubation varies widely; between two and thirty days. The average appears to be from seven to ten days. The so-called abortive cases may act as carriers, and there are also many authentic cases in which the disease was in all probability carried by a third person.

"The duration of the period of infectivity is unknown, which leaves the question of isolation and quarantine unsettled."

THE EFFECT OF ROENTGEN RAYS ON THE THYMUS

That Roentgen rays produce distinct changes in various tissues of the animal body is well known, but concerning the exact mechanism by which these changes are caused we know practically nothing. Marked changes may be produced in the blood and blood-forming organs by these rays under proper conditions and, as first shown by Heineke, the lymphocytes are especially sensitive to their action, disintegration taking place very rapidly. It is on this account that the rays are used in the treatment of leukemia. In animals it has been found that the lymphoid tissues themselves are markedly affected. Recently the effect of roentgenization on the thymus has been studied experimentally by Rudberg,[1] and as the resulting cellular changes have been followed closely (in rabbits) a brief account of them is given.

Under the influence of the rays, the lymphocytes as well as the cells of the reticulum of the thymus rapidly undergo a characteristic destructive process which sets in with disintegration of the lymphocytes within three and one-half hours after beginning the exposure. The products of disintegration, as a rule, do not leave the thymus, but are taken up by the cells of the reticulum and subjected to intracellular digestion, and in from twelve to forty-eight hours all lymphocytes and lymphocytic remnants may have disappeared. The reticulum cells now become closely approximated and the tissues assume an epithelial aspect. Degeneration of the reticulum cells takes place somewhat later, often after all lymphocytes have been destroyed, and continues after the regeneration of lymphocytes has begun. The reticulum cells are changed into large transparent forms with pronounced foamy structure. Large parts of the thymus may become sequestrated and, through softening of the dead tissue, cystic cavities may arise. If the destruction has been moderate only, the regeneration which follows is accomplished by the reticulum cells as well as the lymphocytes still present. But if prolonged exposures are made, then all the lymphocytes may be destroyed and now the new lymphocytes appear to come by importation through the lymph-vessels, passing into the perivascular connective tissue to the center of the lobules and spreading themselves out towards the periphery. Later, these cells multiply and after a time the division of the parenchyma into cortex and medulla becomes apparent again.

Marked changes in the thymus occur also when it is protected against direct action of the rays by means of lead plates. In this case there is not only some disintegration of lymphocytes, but also an emigration. The latter takes place in the usual method characteristic of accidental thymic involution and inanition, the lymphocytes wandering into the medulla and entering the lymph-vessels there. The emigration begins early and is most marked from the second to the fifth day; it may be most marked before the animal begins to show signs of diminished vitality and loss of body weight and, consequently, has no connection with the thymic involution which may result from disturbance of the general condition by roentgenization. It seems that the cells emigrate in order to replace cells that have been destroyed elsewhere in the body and in the blood, and in consequence the number of lymphocytes in the blood increases. The disintegration of the thymic lymphocytes in animals whose thymus is protected takes place during the first day after irradiation and is similar to that which follows direct irradiation but is less extensive. The cause is ascribed in part to a secondary irradiation from the neighboring parts of the body, which have been exposed to the rays, and no doubt in some part to the action of lymphocytolytic substances which appear in the blood and tissue fluids. This secondary irradiation is easily shown by placing a photographic film under the lead plate. That lymphocytolytic substances are produced was shown by Rudberg by injection of the blood and serum of irradiated animals into the peritoneal cavity of healthy animals, in which there resulted a distinct disintegration of lymphocytes in the follicles of the appendix and mesenteric lymph-nodes.

At present we must be satisfied with knowing that Roentgen rays cause the remarkable changes that have been described; how they cause them is a mystery.

THE CARD SYSTEM OF RATING DAIRIES

In a previous issue,[1] the question of dairy inspection was discussed in a general way. It is evident that in order to obtain from dairy inspection results of value in the way of improvement of the milk-supply, a uniform system of inspection must be practiced and careful records kept. This would permit a comparison of the results accomplished and would encourage the improvement of dairies by the dairymen. The most reliable index of the quality of the milk-supply is the bacterial content. Improvement in dairy equipment and methods should be reflected in the bacterial findings.

---

[1] The Journal A. M. A., Jan. 14, 1911, p. 124

In order to secure an efficient system of records and, to facilitate the comparison of results a number of scorecards have been devised. The one most commonly used has been worked out by the Department of Agriculture and covers two features—equipment and methods. Under equipment are considered the health of cows, provisions for their comfort, food and its quality, the construction of stables, bottling rooms, sterilizers and other utensils. Forty points are allowed in the rating for perfect equipment. Under methods are comprised cleanliness of the cows, of the stables, ventilation of the buildings, condition of the utensils, of the milkers, of the milk room, and the methods of handling the milk and its prompt and efficient cooling. For perfect methods, 60 points are allowed.

This card has also on its reverse side a place for recording the number of cows, the number of gallons of milk produced daily and the market to which the milk is sent, and a place for recording the quantity of milk procured from other dairies.

Another system of inspection, used in Michigan, comprises five features, allowing 100 points for each. They cover the health of the herd and its protection, cleanliness, construction and care of utensils, health of employees and manner of milking, and the subsequent handling of the milk. A perfect score would be 500 points. In addition, the general sanitary conditions are noted as good, medium, poor, etc. There is also a provision for recording the quality of milk under the heads of percentage of butter fat, lactometer tests, total solids, and solids not fats.

The card devised by the government has aided much in forming an idea as to correct dairy conditions, but it is far from perfect. The chief criticism is that the details under each of the heads mentioned above are not sufficiently worked out. For instance, the matter of tuberculin tests of the cows, the manner of bedding, the construction of the stable with reference to light, cubic air space per cow, screens in windows, etc., might be given in greater detail, together with more minute details with reference to the condition and manner of using, cleansing and keeping the various utensils. Similarly the cleanliness of the cows, the methods of handling the manure and food and the condition of the milkers are not sufficiently particularized.

It will be seen that much of the value of such records will depend on the knowledge and judgment of the inspector and the thoroughness with which he does his work. For this reason it is highly important that men thoroughly trained should be employed for this purpose. An excellent plan would be to demand from the applicants for such positions that they have certificates from a dairy school in good standing, so that they may have a proper appreciation of the points of clean milk production that would tend most to a low bacterial count. For there must be a definite relation between the score of the dairy and the number of bacteria present in the milk. The higher the score the smaller the number of bacteria, and *vice versa.*

The foregoing has reference, of course, only to the production of milk in the dairies. The control of conditions in milk depots and stores and throughout the distributing system must be carried on in a similar manner.

The advantages to be obtained by a thorough system of inspection and record-keeping would be, first, the accumulation of reliable data concerning the essentials of clean milk production and handling; second, the imparting of instruction to all those engaged in milk production and the milk traffic; third, the establishment of a statistical basis for appropriate legislation. The card-rating system, if developed in sufficient detail, and accompanied by efficient inspection, would be an effective method of securing these results.

THE FUNCTION OF THE CORPUS LUTEUM

Whenever a pathologist presents a summary of the present status of the problem of cancer etiology, he is more than likely to conclude with a statement to the effect that the solution is up to the biologist. This conclusion rests on the conviction that the growth of cancer cells depends on the same fundamental factors as the growth of normal cells, which have in some way become perverted. The pathologist reasons that when the biologist has shown why normal cells proliferate, and especially why they stop proliferating when certain well-defined limits of growth have been reached, it will be a simple matter to find why sometimes the growth processes are of excessive energy or why they fail to stop at the proper time, and by their lawlessness constitute malignant growths. Cellular biology, therefore, seems to hold the key to the genesis of tumors, and cooperation between its disciples and the pathologists seems to offer the best hope of success. As an illustration of this principle we may call attention to the important studies on the growth of tumor cells under the microscope which have been reported in recent numbers[1] of THE JOURNAL, and which are the outcome of the observations on cell growth made by a pure biologist, Professor Harrison of Yale.

Equally interesting advances along the line of cell growth, which have a presumptive bearing on tumor genesis, have been recently made by a reverse process, the incursion of a pathologist into the fields of biology. Leo Loeb, through whose studies America has the credit of the first extended series of successful tumor transplantations. has during the past few years published a number of observations on the function of the corpus luteum which have much significance for both biology and pathology. It may be recalled that the corpus luteum has a histologic structure strikingly similar to that of the adrenal cortex, a fact which makes it probable, if not certain, that this transitory cell mass must possess some function in the way of internal secretion. In consequence of this fact and of sundry experiments, various hypotheses have been evolved, but without the final establishment of the function of the corpus luteum. Through an extensive series of experiments Loeb[2] has now positively determined that this organ, for such it may properly be called, does produce an internal secretion or secretions which exercise an important influence on the sexual cycle. One function of this secretion seems to be that of prolonging the length of time between two successive ovulations, so that during pregnancy the useless discharge of mature ova from the ovary is prevented, whereas if impregnation does not occur the early atrophy of the corpus luteum of menstruation or ovulation permits of more rapid maturation of ova, thus hastening the time of the next possible impregnation.

A., Oct. 15, 1910, p. 1378; Cultivation of Sarcoma Outside of the Body, ibid, Oct. 29, 1910, p. 1551; Nov. 12, 1910, p. 1732. Weil, R.: Biochemical Investigation of Malignant Tumors and Its Diagnostic Applications, ibid, Oct. 29, 1910, p. 1532. See also report of meeting of American Association for Cancer Research, THE JOURNAL A. M. A., July 23, 1910, pp. 340-1; Culture of Cancer Cells *in Vitro*, a letter from G. Volpino, ibid, Jan. 14, 1911, p. 139. Lambert, R. A., and Hanes, F. M.: Growth *in Vitro* of Transplantable Sarcomas of Rats and Mice, ibid, Jan. 7, 1911, and Feb. 25, 1911, p. 587.

Another function, and one that seems especially related to cell growth and tumor formation, is that of sensitizing the uterine mucosa so that it reacts to any sort of mechanical stimulus by forming a maternal placenta. A few days after ovulation the uterine mucosa of the guinea-pig can be made to take on a most exuberant growth, leading to the formation of much placental tissue, by merely introducing into the uterine cavity an inert foreign body, such as paraffin or a bit of glass rod, or by injuring the mucous membrane by incising it. Nervous influences having been excluded, and the essential importance of the corpus luteum in producing this condition having been established, the conclusion is reached that the corpus luteum secretes a hormone with the function of sensitizing the cells of the uterine mucosa so that they react to indifferent mechanical stimuli by rapid proliferation. Normally, this stimulus is furnished by the impregnated ovum, but as any foreign body will have the same effect as the ovum in this respect, the purely mechanical nature of the stimulus is evident.

The close relation of these observations to tumor pathology is at once apparent when we recall the numerous instances in which some mechanical stimulus, whether a blow or chronic irritation, has led to the production of a malignant tumor. Furthermore, experimental studies on tumors in animals have indicated that the power of the malignant tissues to proliferate is influenced by chemical substances of unknown nature, which in some cases seem to stimulate and in others appear to retard cancer growth. The strange behavior of those remarkable placental tumors, the deciduomata, also recurs to one in contemplating the great growths of placental tissue which Loeb has caused to develop in the uterine mucosa as a reaction to mechanical stimuli. To attempt any speculation as to the exact meaning of these experiments for human pathology at this time would, however, be premature.

It may be of interest to the clinician to learn that it is not possible to produce the effects characteristic of the corpus luteum secretion by injecting extracts of the fresh corpora lutea of guinea-pigs or of swine into castrated guinea-pigs.[3] This fact is of importance in view of the proposed and attempted therapeutic use of the same material in practice, although it must be granted that negative experimental results do not absolutely exclude positive clinical results, however improbable the latter may thus be rendered. There seem to be few internal secretions whose normal delivery to the tissues in minute quantities as needed can be successfully replaced by the therapeutic introduction of larger quantities at longer intervals.

EFFORT FOR HIGHER PRELIMINARY STANDARDS

An energetic effort is being made in at least two states to secure legislation providing for a higher standard of education preliminary to the study of medicine. At a meeting of the Ohio State Medical Teachers' Association held in December, a resolution was adopted requesting the Ohio State Medical Board to join the association in petitioning the legislature to enact a law fixing the minimum educational requirement preliminary to the study of medicine at two years of collegiate work, including chemistry, physics, biology and a modern language. Legislation providing for a similar standard is also being asked for in Utah. That standard has been adopted in Minnesota, North Dakota, Colorado, Iowa and Indiana, and a requirement of one year's work in physics, chemistry and biology in addition to a standard four-year high-school education has been adopted in South Dakota, Kansas and Connecticut. It is clear that such requirements on the part of state boards are not unreasonable; twenty-eight colleges are now enforcing the two-year requirement and thirteen others are requiring one year of collegiate work or its equivalent for admission. Of the latter group several have expressed their intention eventually of requiring two years of collegiate work. Should the state boards more generally adopt the increased requirement, it might cause a further reduction in the number of medical colleges, but with our present oversupply that reduction would not be serious. Of much more importance, however, are the facts that this country would have a larger number of medical colleges adhering to reasonably high standards for admission; that a larger percentage of medical students, because of the higher entrance requirements, would be enabled better to grasp the fundamentals of a modern medical training, and that the public would be benefited by having a larger number of educated and well-trained physicians.

A JUDICIAL VIEW OF DRUG ADULTERATION

A New York firm that shipped adulterated drugs into another state was prosecuted under the federal Food and Drugs Act. As the government's case against the firm was clear and unmistakable, a plea of guilty was entered. Judge Holt, of the U. S. Circuit Court for the Southern District of New York, before whom the case was tried, suspended sentence over a term of two years. In so doing Judge Holt criticized the methods employed by the government officials in securing the evidence in the case. It appears that the Department of Agriculture had a San Francisco house order from the New York firm a number of different drugs. They were analyzed and the prosecution was based on the chemists' findings. Judge Holt in his criticism said:

> "I do not propose to aid in this sort of perversion of the law and abuse of its processes. This method of getting evidence in cases of this kind is resorted to by inspectors to show their efficiency through the medium of sham orders under cover of interstate commerce. These things were bought for the purpose of getting up a criminal prosecution instead of legitimate business purposes. This is following out the idea of modern federal legislation and taking the proper relief power from the states."

To the man in the street the action of the government employees in securing evidence against the shippers of adulterated drugs seems entirely praiseworthy. From the standpoint of public health there is no doubt that the adulteration of drugs and foods should be stopped, and at present the federal authorities seem to be about the only ones—with a few notable exceptions—that are competent to check it. Judge Holt apparently thinks that, because the adulterated drugs were not bought for "business purposes" the government authorities were overzealous in proving such adulteration. Evidently, the judge would not approve of the various city weight and measure inspectors because, in pursuit of their duties, they purchase food and other products not for "business purposes," but to determine whether the public is being "short-weighted." Anyone conversant with human nature knows that the strongest incentive to commercial honesty is a well-founded belief that dishonesty is constantly being exposed by the officials whose duty it is to safeguard the public's health and purse. Judge Holt also echoes that oft-heard plaint that, in prosecuting "patent-medicine" fakers, drug adulterators and food sophisticators, the federal government is encroaching on the powers of the state! For years before the Food and Drugs Act went into effect the various states had laws which were supposed to protect the public against adulteration in drugs and foods, but the enforcement of these state laws was—and in many cases still is—the veriest of farces. Zealousness on the part of officials who were supposed to enforce the state pure food and drugs laws usually resulted disastrously to such officers, with the result that many state food and drug inspectors were satisfied to become mere salaried figure-heads. If the same opposition is going to be brought against federal officers who have the public health, rather than the "business interests" at heart, we may look for the government officials to develop the same apathy that has paralyzed many of the state food and drugs acts and made state enforcements of law a byword and a reproach. If there is anything the "business interests" like better than a considerate congressman, it is a solicitous judge.

ATHLETICS IN THE NAVAL ACADEMY

In his recent report, the Surgeon-General of the Navy calls attention to a point which may be of some importance: that is, the danger of too strenuous athletic training for naval officers. It has long been observed that highly developed muscles do not always accompany a high resistance to infection, but often weaken resistance by producing an imbalance between the different organic functions. It has frequently been noticed, for example, that many athletes die of tuberculosis. The frequency, perhaps, is apparent rather than real, since an athlete's death from tuberculosis is sure to be remarked because it seems unexpected. It is almost certain, nevertheless, that athletes do not possess any exemption from that disease because of their splendid physical development, and it is even probable that this very fact may increase their liability. Naval officers in active service are confined within rather narrow quarters and have little opportunity to keep up the physical activities that an overtrained and overdeveloped physical organization may need. An excessive muscular development that is not demanded by the occupational activities of the individual becomes a parasitic element in the organism; that is to say, instead of contributing to the individual's total efficiency, the activities required by such a muscular development make drafts on the individual's time and energies and actually decrease his efficiency. Under such circumstances it becomes a positive detriment instead of a benefit.

A CORPORATION WITH A CONSCIENCE

In his last annual message President Taft recommended legislation against the use of white phosphorus in the manufacture of friction matches as causing one of the most serious of occupational diseases. A bill was introduced into Congress acting on this recommendation, but it appears that the use of any substitute had been covered by a patent held by the Diamond Match Company. This fact imperiled the passage of the bill, even if the enforcement of the patent right was not absolutely insisted on by the holder, as Congress thought it could not legislate away a right legally bestowed, even if it was only nominally held. To meet this objection the company has voluntarily surrendered its rights and dedicated the patent to the use of the people of the United States. As the *Outlook* says, this action, whi it may be in some measure dictated by enlightened sel interest, deserves cordial commendation.

tations, has during the past few years published a number of observations on the function of the corpus luteum which have much significance for both biology and pathology. It may be recalled that the corpus luteum has a histologic structure strikingly similar to that of the adrenal cortex, a fact which makes it probable, if not certain, that this transitory cell mass must possess some function in the way of internal secretion. In consequence of this fact and of sundry experiments, various hypotheses have been evolved, but without the final establishment of the function of the corpus luteum. Through an extensive series of experiments Loeb[2] has now positively determined that this organ, for such it may properly be called, does produce an internal secretion or secretions which exercise an important influence on the sexual cycle. One function of this secretion seems to be that of prolonging the length of time between two successive ovulations, so that during pregnancy the useless discharge of mature ova from the ovary is prevented, whereas if impregnation does not occur the early atrophy of the corpus luteum of menstruation or ovulation permits of more rapid maturation of ova, thus hastening the time of the next possible impregnation.

Another function, and one that seems especially related to cell growth and tumor formation, is that of sensitizing the uterine mucosa so that it reacts to any sort of mechanical stimulus by forming a maternal placenta. A few days after ovulation the uterine mucosa of the guinea-pig can be made to take on a most exuberant growth, leading to the formation of much placental tissue, by merely introducing into the uterine cavity an inert foreign body, such as paraffin or a bit of glass rod, or by injuring the mucous membrane by incising it. Anyone conversant with human nature knows that the strongest incentive to commercial honesty is a well-founded belief that dishonesty is constantly being exposed by the officials whose duty it is to safeguard the public's health and purse. Judge Holt also echoes that oft-heard plaint that, in prosecuting "patent-medicine" fakers, drug adulterators and food sophisticators, the federal government is encroaching on the powers of the state! For years before the Food and Drugs Act went into effect the various states had laws which were supposed to protect the public against adulteration in drugs and foods, but the enforcement of these state laws was—and in many cases still is—the veriest of farces. Zealousness on the part of officials who were supposed to enforce the state pure food and drugs laws usually resulted disastrously to such officers, with the result that many state food and drug inspectors were satisfied to become mere salaried figure-heads. If the same opposition is going to be brought against federal officers who have the public health, rather than the "business interests" at heart, we may look for the government officials to develop the same apathy that has paralyzed many of the state food and drugs acts and made state enforcements of law a byword and a reproach. If there is anything the "business interests" like better than a considerate congressman, it is a solicitous judge.

ATHLETICS IN THE NAVAL ACADEMY

In his recent report, the Surgeon-General of the Navy calls attention to a point which may be of some importance: that is, the danger of too strenuous athletic training for naval officers. It has long been observed that highly developed muscles do not always accompany a high resistance to infection, but often weaken resistance by producing an imbalance between the different organic functions. It has frequently been noticed, for example, that many athletes die of tuberculosis. The frequency, perhaps, is apparent rather than real, since an athlete's death from tuberculosis is sure to be remarked because it seems unexpected. It is almost certain, nevertheless, that athletes do not possess any exemption from that disease because of their splendid physical development, and it is even probable that this very fact may increase their liability. Naval officers in active service are confined within rather narrow quarters and have little opportunity to keep up the physical activities that an overtrained and overdeveloped physical organization may need. An excessive muscular development that is not demanded by the occupational activities of the individual becomes a parasitic element in the organism; that is to say, instead of contributing to the individual's total efficiency, the activities required by such a muscular development make drafts on the individual's time and energies and actually decrease his efficiency. Under such circumstances it becomes a positive detriment instead of a benefit.

A CORPORATION WITH A CONSCIENCE

In his last annual message President Taft recommended legislation against the use of white phosphorus in the manufacture of friction matches as causing one of the most serious of occupational diseases. A bill was introduced into Congress acting on this recommendation, but it appears that the use of any substitute had been covered by a patent held by the Diamond Match Company. This fact imperiled the passage of the bill, even if the enforcement of the patent right was not absolutely insisted on by the holder, as Congress thought it could not legislate away a right legally bestowed, even if it was only nominally held. To meet this objection the company has voluntarily surrendered its rights and dedicated the patent to the use of the people of the United States. As the *Outlook* says, this action, while it may be in some measure dictated by enlightened self-interest, deserves cordial commendation.

Medical News

ALABAMA

New Sanatorium.—Dr. Francis G. Dubose will remodel the old parsonage of the First Baptist Church, Selma, as a sanatorium to replace the Vaughan Memorial Hospital which was destroyed by fire, January 5. The reconstruction of the building is estimated to cost $12,000.

Personal.—Drs. R. F. Lovelady and William W. Long, Birmingham, have been elected directors of the American Health and Accident Insurance Company.——Dr. William M. Jordan, Birmingham, who has been under treatment in Johns Hopkins Hospital, Baltimore, has returned home.——Dr. Carney G. Laslie has been elected health officer of Montgomery, vice Dr. Rufus L. Milligan, resigned.——Dr. William Y. White has been appointed health officer of Anniston, vice Dr. Thomas J. Brothers.——Dr. Thomas G. Howard, Selma, has been elected health officer of Dallas County.

ARKANSAS

Personal.—Drs. Early E. Scott, Magazine; James J. Smith, Paris, and William F. Paskerville, Booneville, have been appointed members of the board of health of Logan County.

State Society Meeting.—The thirty-fifth annual session of the Arkansas Medical Society will be held at Fort Smith, May 2-5. The society will be guests of the Sebastian County Medical Society.

Advises Removal of State Hospital.—The committee appointed some time ago by the Board of Trustees of the State Charitable Institutions to investigate the feasibility of the removal of the State Hospital for Nervous Diseases, reported favorably on the proposition, and the report has been approved by the board. It was the unanimous sentiment of the board that the hospital should not be removed from Little Rock, and a committee was appointed to seek an available site for the institution.

CALIFORNIA

Tuberculosis Society to Incorporate.—At the annual meeting of the San Francisco Association for the Study and Prevention of Tuberculosis, held January 31, the election of officers and directors was deferred until February 23, when it was voted to hold an adjourned meeting, that time might be given to discussion of articles of incorporation, etc.

Personal.—Dr. Thomas A. Stoddard, health officer, and Drs. Samuel B. P. Knox and David A. Conrad, members of the board of health of Santa Barbara, have resigned.——Dr. Emma K. Willits, San Francisco, was seriously injured, February 3, by a collision between her automobile and another machine.——Dr. William H. Stokes has been appointed a member of the board of health of Whittier.——Dr. Charles L. King, Pasadena, who was injured in an automobile accident recently, is reported to be convalescent.——Rea N. Smith, Los Angeles, who was sued for malpractice, won the verdict, February 7.

GEORGIA

New City Hospital Started.—At a mass meeting, held in Augusta in the interest of the medical college and a greater city hospital, more than $14,500 was subscribed, making the total amount pledged now $25,200.

Physician Seeks Runaway Son.—Dr. Andrew J. Mann, Alvaton, fearing that his son, William Worcester Mann, has run away, will greatly appreciate any information that may lead to his return. Dr. Mann may be reached at Alvaton by Bell telephone, collect, and at Haralson by telegraph, collect. The description is as follows: age, 16½ years; height, 5½ feet; weight, 150 pounds; broad shoulders and hips; brunette complexion; dark-brown, sharp eyes; dark-brown, curly hair; low bass voice; fine set of even teeth; hat, No. 7; shoes, No. 8; French twilled worsted, dark-blue suit; patent leather slippers; scar across toes of right foot.

Hookworm Conference.—The Rockefeller Commission held a conference in Atlanta, February 14-16, at which the field
he commission organized for the destruction of
m, and planned a campaign to be waged against
nvestigations in Georgia disclose the fact that
f 145 counties in the state, hookworm has been
n the remaining 7 counties, investigation has not
far enough to make a full report. Reports
the conference on the prevalence of hookworm
n states as well as in the south. A uniform
ing reports and records was adopted.

ILLINOIS

Small-Pox in State Hospital.—Three patients of the Elgin State Hospital are confined in the hospital infirmary suffering from what is said to be a mild form of small-pox.

Local Medical Society Elects.—The Alton Medical Society has elected Dr. J. A. Cook, president; Dr. J. Bernard Hastings, secretary, and Dr. Waldo Fisher, treasurer.

Fined for Distributing Nostrum.—B. J. Crowe is said to have been fined $5 and costs, amounting in all to $9.25, in Freeport, February 14, for violating the section of the city ordinance which prohibits the promiscuous distributing of "patent medicines."

The Fight Against Tuberculosis.—Nearly $13,000 will be available for the antituberculosis work in Illinois during the present year as the result of the Red Cross Christmas Seal campaign. The total number of seals sold in Illinois was 1,652,869.

Popular Medical Lectures.—The physicians of Alton, with the indorsement of the Alton and Madison County Medical societies, have undertaken a series of lectures on medical subjects to be given every two weeks for school children and their parents. The following will be the program of the lectures:

February 19.—"Infectious Diseases: Invasion, Attack, How Controlled." Dr. James M. Pfeiffenberger.
March 3.—"Tuberculosis; Prevention and Care of Disease.' Dr. J. Bernard Hastings.
March 17.—"Diseases of Eye." Dr. Fred W. Jones.
March 31.—"Diseases of Nose and Throat." Dr. George E. Wilkinson.
April 7.—"Fresh Air and Exercise." Dr. N. Garland Taphorn.
April 21.—"Sick Room Management." Dr. Homer W. Davis.
May 5.—"Mental Defects." Dr. William H. C. Smith, Godfrey.
May 19.—"Care and Feeding of Babies." Dr. Frederick C. Joesting.
May 29.—"Care of Teeth." R. E. Cockerell, D.D.S.

Chicago

Dispensary Opened.—The Iroquois Memorial Dispensary opened for its first clinic for tuberculosis patients, February 21. The clinic was in charge of Dr. Clarence L. Wheaton.

Take Interest in Mayoralty Campaign.—More than 200 physicians have formed a Charles E. Merriam Club and elected the following officers: president, Dr. John M. Dodson; vice-presidents, Drs. Homer V. Halbert, Isaac N. Dansforth, Albert J. Ochsner and James E. Stubbs; secretary, Dr. Ludvig Hektoen, and treasurer, Dr. Winfield S. Harpole.

Tuberculosis Hospital Staff Named.—The president of the county board announced, February 14, the following attending staff for the Tuberculosis Hospital located on the county hospital grounds: chief of staff, Dr. Clarence W. Leigh, and members, Drs. Thomas A. Hogan, Clyde D. Pense, Frederick Tice, Arthur M. Corwin, Milton Mandel and George B. Dyche.

Benefited by Charity Ball.—The final report of the chairman of the committee which had in charge the Charity Ball, shows that $26,599.08 is the net sum to be distributed. Of this the Children's Memorial and Presbyterian hospitals each receive $5,500, the Alexian Brothers', Chicago Lying-In, The Passavant Memorial, and Provident hospitals, and the visiting Nurses' Association, each $2,250, and the German Hospital, $1,000.

INDIANA

Pettigrew Discharged.—Charles G. Pettigrew, Logansport, whose license was revoked by the State Board of Medical Examiners, and who was arrested on the charge of practicing medicine without a license, was discharged as he proved that he had turned over all his business to licensed practitioners.

New Cottage for Camp Colony.—As the result of the efforts of the South Bend Antituberculosis League, the local colony is to be benefited by at least two new cottages, funds for which have been appropriated by the state committee of the American National Red Cross. The following is the newly elected medical staff of the league: chairman, Dr. Edwin J. Lent; superintendent, Dr. W. H. Hillmann, and Drs. Charles E. Hansel, Roscoe L. Sensenich, Hugh M. Miller, Walter H. Baker, and Charles S. Bosenbury.

Personal.—Dr. William G. Ralston, Evansville, celebrated his ninety-second birthday anniversary, February 13.——Dr. Homer H. Elmore, Brown Valley, was ordained as a clergyman of the Baptist Church, February 2.——Dr. Alfred Henry has been appointed chief of the Indianapolis Free Tuberculosis Clinic, vice Dr. Jewett V. Reed, resigned.——Dr. Charles L. Dreese, Goshen, is reported to be seriously ill.——Dr. Samuel E. Smith, medical superintendent of the Eastern Indiana Hospital for the Insane, East Haven, Richmond, has been appointed chairman of the executive committee of the Twentieth Indiana State Conference of Charities and Corrections.

IOWA

Personal.—Dr. Frederick G. Ellis, of the staff of Mount Pleasant Hospital, has resigned.——Dr. and Mrs. J. W. Grillin, Manson, have returned from Germany.

Appropriation Asked for Epileptic Hospital.—The bill of the State Board of Control, asking for an appropriation of $200,000 for a state epileptic hospital has been presented in the senate by Senator Jewell.

Society Meetings.—The physicians of the southern part of Page County, met at Coin, completed the organization of the Page County Medical Protective Association, and elected Dr. Allen H. King, Coin, president; Dr. Robert W. Blanchard, vice-president; Dr. William G. Johnson, Coin, secretary, and Dr. John R. Thompson, Northboro, treasurer.——At the annual meeting of the Waterloo Medical Society, Dr. J. Q. A. Scroggy was elected president; Dr. W. M. Sterling, vice-president; Dr. Joseph R. Allen, secretary, and Dr. DeWitt C. Hunton, censor.

KANSAS

Personal.—Dr. Owen G. Hutchinson has been appointed physician of Wichita and of Sedgwick County.——Dr. Charles W. Ewing, Wellsville, announces that he is about to cease practice.

Sanatorium Recommended.—The senate in committee of the whole, February 3, recommended for passage the bill of Senator Milligan, providing for the establishment of a sanatorium for tuberculosis patients at some point in western Kansas to be selected by the State Board of Control. The bill carries an appropriation of $25,000 for the establishment of the sanatorium, and is approved by the State Board of Health.

LOUISIANA

Society Moves to Its New Home.—The Orleans Parish Medical Society has occupied the new building recently erected for it on the corner of Elk Place and Gasquet Street, at a cost of $15,000. The lower floor contains the office of the secretary, the library and reading room, and on the floor above is the assembly room with a seating capacity of 200.

Sanitation of Barber Shops.—At a meeting of the state Board of Health, January 20, an ordinance was adopted providing that owners of barber shops shall register their names and place of business not later than July 1, that they must keep hot and cold water, must sterilize their instruments after shaving each person, and prohibiting barbers from treating any person for skin disease, or from shaving any person with skin disease unless the individual furnish his own razor, brush and mug.

MARYLAND

Personal.—Dr. Harry M. Bowen, Aquasco, has been appointed a member of the Board of Commissioners of Prince George County.——Dr. Arthur L. Wright, pathologist to the Maryland Hospital for Insane, near Catonsville, has resigned to accept a position on the medical staff of the Baltimore and Ohio railroad.

Baltimore

Leprosy in Baltimore.—The diagnosis of leprosy is said to have been made in the case of a Chinaman held for observation at the Baltimore Quarantine. The patient is a carpenter on the British Steamer *Eskdale*, which arrived at Baltimore from Liverpool, via Huelva, February 2.

Interest in Health Conference.—Great interest was displayed in the public health conference last week under the auspices of the Medical and Chirurgical Faculty of Maryland. Sessions were well attended and many were crowded, the exhibits also attracting large numbers of people. Among the chief subjects discussed were dress, house, milk, training of children, care of the feeble-minded, etc. As the meetings were so successful, and the public so eager for information, it is proposed to repeat the meetings annually.

Personal.—Dr. Samuel C. Chew was reelected president, and Dr. Henry Barton Jacobs, member of the board of trustees of the Peabody Institute, at a meeting February 13.——Dr. Duncan McCalman was thrown from his automobile in a collision, February 16, sustaining injuries to the back and eye.——Dr. George W. Mahle has been compelled to abandon the practice of medicine on account of ill health.——Dr. Howard J. Maldies has been made lecturer on pathology and bacteriology in the Department of Dentistry of the University of Maryland.——Dr. John C. Hemmeter made an address at the annual meeting of the Pennsylvania Branch of the University of Maryland Alumni at their meeting in Harrisburg, February 23.——In a recent suit, Dr. George W. Dobbin has been awarded $3,800 for damages received in a collision of automobiles.

MICHIGAN

Dinner to Dr. Connor.—A dinner was given by the medical friends of Dr. Leartus Connor at the Detroit Club, February 23, *in commemoration of the fortieth year of his entrance into practice. The committee in charge consisted of Drs.* Justin E. Emerson, Andrew P. Biddle, Arthur D. Holmes, George E. Frothingham, and Benjamin R. Schenck.

MINNESOTA

Society Organized.—The Minnesota Academy of Ophthalmology and Oto-Laryngology was organized in Minneapolis, February 8. The following officers were elected: president, Dr. Howard McI. Morton, Minneapolis; vice-presidents, Drs. Jehiel W. Chamberlin and John F. Fulton, St. Paul, and secretary-treasurer, Dr. Elmer H. Parker, Minneapolis.

Reorganization of State Board of Examiners.—A partial reorganization of the State Board of Medical Examiners was announced by the governor February 16. The new members are as follows: Dr. Frank R. Weiser, Windom, Cottonwood County, to succeed Dr. Thomas Lowe, Pipestone; Dr. Hannah Hurd, Minneapolis, to succeed Dr. Margaret Koch; and Dr. Robert D. Matchan, Hennepin County, to succeed Dr. Frederick A. Knights, Minneapolis, the terms of all to expire January, 1914.——Anton Taylor has been appointed a member of the State Board of Osteopathic Examiners, vice G. L. Huntington.

Personal.—At the annual meeting of the Minnesota Association for the Prevention and Relief of Tuberculosis, Dr. Harry A. Tomlinson, St. Peter, was elected president; Dr. Warren L. Beebe, St. Cloud, as vice-president; and Dr. Henry L. Taylor, St. Paul, secretary.——The offices of Dr. Frank R. Weiser and Dr. Abanson, Windom, were totally destroyed by fire, February 2.——Dr. Edward M. Gans, formerly surgeon in charge of More Hospital, Eveleth, has resigned and expects to remove to Dickinson, N. D.——Dr. Pane B. Cook has been appointed assistant health commissioner of St. Paul.——Dr. Francis R. Woodard, Minneapolis, has been elected chief, and Dr. Willard B. Pineo, secretary of the staff of Asbury Hospital, Minneapolis.——Dr. Walter J. Marcley, superintendent of the State Tuberculosis Sanatorium, Walker, has been appointed secretary and executive agent of the State Tuberculosis Commission.

MISSOURI

St. Louis

Transfer of Insane Patients.—Arrangements have been made for a special train to bring to St. Louis insane patients who are charges of St. Louis, and who have been temporarily housed at the state hospitals at Fulton and Farmington.

Hospital to be Renamed.—A bill formally to change the name of Quarantine Hospital to Robert Koch Hospital was introduced before the municipal assembly, February 10, at the instance of the hospital board. The institution is now being used for the care of cases of tuberculosis.

NEW YORK

Antivaccination Bill.—Among the bills recently introduced into the legislature is one by Assemblyman Boylan providing that unvaccinated children may be admitted to the public schools on certificates of a physician that their physical condition is such that vaccination would jeopardize their health, or on written declaration from their parent or guardians stating that they are conscientiously opposed to vaccination.

Opens Crusade Against Insanity.—The State Charities Aid Association has issued its first pamphlet on insanity, in which it is stated that one-sixth of the total expenditures of the state is for the insane. The amount spent is equal to an annual tax of 70 cents on every man, woman and child in the state. The preventable causes of insanity—immoral living, alcohol and other poisons, physical diseases and mental habits—are enumerated and the belief is stated that insanity cannot be inherited and that only a tendency may be transmitted. A wider knowledge of the causes of insanity is recommended as one of the most effective means of combating it.

Wiley and Cabot in Buffalo.—Dr. Harvey W. Wiley, chief of the Bureau of Chemistry of the Department of Agriculture, Washington, D. C., delivered a lecture recently before the Buffalo Academy of Medicine, Medical Society of the County of Erie, Western New York Section of the American Chemical Society, and the Erie County Pharmaceutical Association on "Public Health Our Greatest Asset." A visit was paid to Niagara Falls and the various chemical industries there, and a dinner was given in honor of Dr. Wiley.——Dr. Richard C. Cabot, Boston, recently delivered a lecture before the Buffalo Branch of the American Prophylaxis Society on "Training of the Affections."

New York City

Receipts from Charity Ball.—The financial results of the German Charity Ball were $11,000, which has been distributed as follows: German Hospital and Dispensary, $2,000; St. Mark's Hospital, $1,300; St. Francis' Hospital, $1,300; German Polyclinic, $1,300; Isabella Home, $1,000; German Dispensary of the West Side, $900; German Ladies' Aid Society, $900 and Wartburg Orphan Asylum, $1,000.

New Building at Sloane Hospital.—To provide for the enlarged scope of the work at the Sloane Hospital for Women a new building for gynecologic cases has been erected. This will be open for inspection Wednesday, March 1, from 2 until 6 o'clock. The original name of the hospital, the Sloane Maternity Hospital, was changed in December, 1910, to the Sloane Hospital for Women, in order to correspond with the extended character of the work. The hospital is located at the corner of Fifty-Ninth Street and Tenth Avenue, the entrance being on Tenth Avenue.

Psychoanalytic Society Organized.—The New York Psychoanalytic Society was organized at a meeting, held February 12. The object of the society is the study of abnormal psychology, advancement of psychoanalysis, and to promote fellowship among psychopathologists. Meetings are to be held on the fourth Tuesday of each month. The society will be incorporated and become affiliated with the parent organization in Zurich, Switzerland. The following officers have been elected: president, Dr. Abraham A. Brill, New York City; vice-president, Dr. Bromislaw Onuf, Amityville, L. I.; and secretary-treasurer, Dr. Horace W. Frink, New York City.

OHIO

Diphtheria Carriers.—"Diphtheria Ernest," a boy of 7, has been found in a Cleveland school, after having infected nineteen other children in the course of several months. The boy is said to be perfectly well, and never to have contracted diphtheria. Throat cultures of 75 other children of the school showed two other diphtheria carriers.

Personal.—Dr. Frank Pennock, Marlboro, whose right arm was amputated at the shoulder at Ingleside Hospital, Canton, February 14, on account of septicemia due to an operation wound, is reported to be orge W. Crile has been appointed chief o staff of Lakeside Hospital, Cleveland.——Dr. Ross V. Dickey, Lima, is reported to be critically ill at his home as the result of cerebral hemorrhage.——Drs. William T. Howard and William T. Corlett, Cleveland, have started for Europe.——Dr. Samuel W. Kelley, Cleveland, is taking a trip to the Bermudas.——Dr. Charles E. Briggs has been appointed visiting surgeon and head of the surgical dispensary, and Dr. Harvey A. Becker, visiting surgeon to Lakeside Hospital, Cleveland.

PENNSYLVANIA

Philadelphia

Personal.—Dr. Aloysius J. Kelly, who has been quite ill for some time, is improving.——Dr. Charles Lincoln Furbush sailed for Europe, February 18.——Dr. S. Weir Mitchell celebrated the 81st anniversary of his birth on February 15.——Dr. Brooke M. Anspach has been made visiting surgeon to the Gynecean Hospital.

Gifts to the College of Physicians.—After the scientific program, at the session of the College of Physicians, February 1, Dr. Robert Abbe, New York City, presented to the college the gold watch of Benjamin Rush, and Dr. William W. Keen, on behalf of the donors, presented to the college a portrait of Dr. William Goodell, the noted gynecologist.

Millions Needed to Relieve Blockley.—Mayor Reyburn hopes to ure from the present legislature nearly $1,000,000
ning of several charitable projects: $350,000 for a
al building at the Philadelphia Hospital, and
half the cost of a building for feeble-minded
ildren. These bills were introduced simultane-
house and senate February 15.

Students to Aid Grenfell.—Students of the
Pennsylvania are making plans to send a del-
p Sir Wilfred T. Grenfell in his medical missionary work among the deep sea fishermen of Labrador. Louis F. Fallon, a sophomore, is in charge of the movement and he is collecting money for the building of a $1,000 launch to be called the *Pennsylvania* and to be used in cruising along the Labrador coast in the service of Dr. Grenfell.

Report of the Milk Commission.—The report of the commission appointed by Mayor Reyburn to investigate the city's milk supply and recommend measures to place it on a sanitary basis profitable to the producer and acceptable to the consumer, was presented to the mayor by Dr. Charles Furbush, chairman of the commission, on February 16. The commission recommended a state-wide inspection of the milk supply by the city authorities in connection with the State Live Stock Sanitary Board; the establishment of a department of milk supervision with a chief supervisor and thirty-five inspectors in the country and thirty-two in the city; an increase in the price of milk of 1 cent a quart to the consumer; a minimum all-year-round price of 5 cents a quart to be paid to the producer; inspection of restaurants, ice cream manufactories, drug stores and all places where milk is sold; establishment by the city of pasteurizing plants.

SOUTH DAKOTA

Auxiliary to State Association Organized.—The wives of members of the South Dakota State Medical Association met at Hot Springs last fall, and formed a woman's auxiliary to the South Dakota State Medical Association, the object being purely social and for the exchange of ideas. The next meeting of the auxiliary will be held in Pierre in June. Mrs. Rudolph D. Jennings, Hot Springs, is president; Mrs. Silas M. Hohf, Yankton, vice-president; Mrs. Harry T. Kenney, Pierre, secretary; and Mrs. Charles S. O'Toole, Vienna, treasurer.

Sanatorium Completed.—The State Tuberculosis Sanatorium, Custer, has been completed by the contractor and is ready to be turned over to the state. Three buildings have been erected, one for the superintendent's residence, the second, a cottage to be used as a dining room and kitchen, with a laundry in the basement, and offices for medical staff, and the third containing sleeping rooms, parlor and library. The board of control will, it is reported, ask for a further appropriation by the state of $54,000 for another building, and $50,000 for maintenance of the institution.

WISCONSIN

Personal.—Dr. Frank R. Weston, LaCrosse, has been appointed medical examiner of the local pension board.——Dr. Arthur W. Rogers has been elected president of the Oconomowoc Health Resort.

State Board Election.—At the annual meeting of the State Board of Health in Madison, January 27, Dr. William F. Whyte, Watertown, was reelected president, and Dr. Cornelius A. Harper, Madison, secretary. The board extended the order against common drinking-cups to all public buildings.

GENERAL NEWS

Research Fellowship.—The accumulated income of the Corinna Borden Keen Research Fellowship of the Jefferson Medical College, Philadelphia, now amounts to $1,000. The fellowship will be awarded by the trustees on recommendation of the faculty to a graduate of Jefferson of not less than one nor more than ten years' standing, on the condition that he spend at least one year in Europe, America, or elsewhere, wherever he can obtain the best facilities for research in the line of work which he shall select after consultation with the faculty, and that he shall publish at least one paper, embodying the results of the work as the "Corinna Borden Keen Research Fellow of the Jefferson Medical College." Applications should be made to Dr. James W. Holland, dean of the college.

The German Hospital of New York.—On the occasion of its fortieth anniversary the governing board of the German Hospital of New York has published a very complete history of the hospital. Those connected with this institution may well be proud of its growth and activities. Accompanying this pamphlet is a *Festschrift* of 593 pages containing contributions by the medical staff of the hospital and its dispensary. These papers are credited to the various services, fourteen to the medical, thirteen to the surgical, five to the gynecologic, four to the ophthalmologic, five to the dermatologic and venereal, and the remainder to the neurologic, ear, nose and throat, dental and laboratory departments, fifty in all. The material comprises the results of observations made on patients and experimental studies in the laboratory and is a valuable addition to medical literature.

FOREIGN NEWS

Bequest by Physician to Found Asylum.—A Spanish physician, Señor Don J. Garcia, who recently died at Valencia, left part of his fortune to found an asylum there for deaf-mutes and the blind.

Statue to Albarran.—The town of Sagua la Grande in Cuba has recently erected a marble statue of "its most illustrious son," Professor Joaquin Albarran, chief of the clinic at Paris for disease of the urinary apparatus. He succeeded Guyon in this much-coveted post in 1906. The statue was erected by popular, nation-wide subscription; a memorial tablet was also placed on the house where he was born.

Fine for Methyl Alcohol Adulteration of Brandy.—Last year a number of serious cases of poisoning at Budapest were traced to the use of a special make of brandy. Investigation revealed that methyl alcohol had been used in its production and was evidently responsible for the poisoning. The distiller was recently sentenced to pay a fine of $2,800 for involuntary homicide resulting from neglect of due caution.

Honor for Professor Schwalbe.—The honorary title of Geheimer Sanitätsrat has been conferred on Professor J. Schwalbe of Berlin, editor of the *Deutsche medizinische Wochenschrift*, of the medical directory for Germany, of a year-book and of several manuals and treatises. Professor Schwalbe, although only 49 years old at present, has long taken a leading part in all matters affecting the welfare of the profession and especially in the propaganda for reform of nostrum abuses.

Deaths in the Profession Abroad.—In addition to the deaths reported by our correspondents, the profession has lost recently Professor G. Profeta of Florence, one of the leading dermatologists of Italy until his retirement a few years ago, author of several manuals on dermatology and syphilis but best known by his assertion that a non-syphilitic child born of syphilitic parents is immune—the so-called Profeta's law.——T. Noriega, professor of pathology and history of medicine at Mexico.——Prof. J. M. Bandera, a prominent ophthalmologist and leader in medical affairs in Mexico, and member of various ophthalmologic and medicolegal societies at home and abroad, aged 73.

LONDON LETTER

(From Our Regular Correspondent)

London, Feb. 11, 1911.

A Revolution in Bread

A remarkable agitation in favor of more nutritious bread than the ordinary white bread which is almost exclusively eaten by all classes has produced an immense change in the bread supplied by bakers. White bread, introduced as a luxury for the rich, has been adopted by all classes. In order to obtain the more attractive white appearance valuable ingredients contained in the germ and inner husk of the wheat and consisting of protein and salts are removed. Prominent among the evils attributed to the consumption of white bread is dental caries, which is so prevalent and severe that it may be described as a national disaster. In the presence of this great evil of removing from the most important food some of its most valuable ingredients, the medical profession has been very supine. From time to time an occasional article has appeared in medical journals pointing out the defects of white bread, but it has had no more effect than the periodical wail on the abandonment of blood-letting. The only persons who have shown themselves alive to the situation are the vegetarians, who in renouncing most animal foods have shown a keen desire to get as much as possible out of their vegetable food; they have always consumed whole-meal bread. But outside their own sect they have no influence. One association, the "Bread and Food Reform League," somewhat allied to the vegetarians, has for years made praiseworthy attempts to advocate the use of whole-meal bread and has pointed out that much of the underfeeding of the poor is due to ignorance of the value of this bread rather than to want of means. But their words have fallen on deaf ears and it is very difficult to obtain a good whole-meal bread. The bakers sell an inferior article, a brown loaf which is made from a mixture of ordinary white flour with a little bran. In the lay press an agitation in favor of the old cream-colored loaf which is termed "standard bread," and defined as "bread made from unadulterated wheat and containing at least 80 per cent of the whole wheat, including the germ and semolina," has produced such an effect in a few days that the result must be described not as a reform in but as a revolution in bread. Prominent physicians and health officers are supporting the movement. It is proposed to introduce a bill into parliament for the standardization of bread and the proposal has received the support of members of all parties.

Great Increase of Street Accidents Due to Motor Traffic

An alarming increase in the number of street accidents from the recent development of motor traffic is shown by the report issued by the Highways Protection League. In 1905, thirty-five persons were killed and 1,557 injured by accidents due to motor traffic, while 118 were killed and 6,323 injured by horse traffic. In 1909, 163 persons were killed and 6,579 were injured by motor traffic, while 123 were killed and 5,589 were injured by horse traffic.

Daring Experiment of a Physician on Himself with Typhoid Bacilli

Dr. Houston, director of water examination to the Metropolitan Water Board, has made a daring experiment on himself with typhoid bacilli. He was testing the effect of river water on the vitality of typhoid bacilli which had never been subcultured. He found that the bacilli rapidly perished in Thames water. Although well satisfied with the negative results, he put the matter to the crucial test of drinking half a pint of the infected water (which contained initially 218 million typhoid bacilli) on the twenty-fourth day from the start of the experiment without any ill result. In the discussion which followed the reading of this report, Dr. R. M. Beaton, chairman of the water examination committee, suggested that as the punishment of hanging was a rude practice experiments of this kind should be made with condemned criminals.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Feb. 3, 1911.

Antityphoid Vaccination

During the discussion on the etiology and prophylaxis of typhoid fever last year at the Académie de médecine, on motion of Professor Chantemesse, a commission was appointed to study antityphoid vaccination (The Journal, March 5, 1910, p. 804). Dr. H. Vincent, for the commission, has just laid before the academy a report to the following effect: The facultative use of antityphoid vaccination should be recommended as a practical and rational means of diminishing the frequency and gravity of typhoid fever in France and in the colonies. This recommendation is addressed to all whose profession, usual or accidental conditions of food or habitat, daily or frequent relation with persons or bacillus carriers, expose them to direct or indirect contagion. This proposition brought forth vigorous protests from Dr. Delorme, *médecin inspecteur général* of the army, who considers the conclusion of the commission as premature and overdrawn. While recognizing that antityphoid vaccination is, at present, of interest to scientific and administrative circles, Dr. Delorme believes that in view of the well-known imperfections of the method (incomplete immunization, negative phase, local and general complications, numerous contra-indications) the Académie de médecine, the counselor of the public authorities, is scarcely authorized to recommend the employment, even facultative, of methods which are still so uncertain, imperfect and cumbered with so many disadvantages and even dangers.

The Health Resorts and Spas of France

A parliamentary group has recently been formed to promote the interests of the thermal and climatic stations of France. It already comprises more than 100 senators and deputies. Its program includes: (1) investigation into the means to give the greatest effect to the law taxing transients at such resorts, passed in 1910 (The Journal, April 23, 1910, p. 1388); (2) creation of a chair of hydrology and climatology at the Faculté de médecine de Paris; (3) creation of a great institute of hydrology and climatology which shall centralize all the chemical, physical, geologic and mineralogic researches needed by our stations to extend their usefulness and to complete the instruction of young physicians who wish to specialize in hydrology and climatology.

The law imposing a tax on visitors will furnish important revenues for the improvement of the hygiene of the stations, and their embellishment, etc. The creation of a chair of hydrology and climatology at the Faculté de médecine de Paris has been demanded for twenty years by all the congresses on hydrology and by associations of physicians interested in the subject. The innovation will have the greater chance of success because it will cost the government nothing, since the

Syndicat des stations thermales de France, which is directly interested in the question, has undertaken to provide the expense of the chair. The only condition imposed by the *syndicat* on its gift is that the professor appointed shall be competent, and shall promise to regard the position as permanent, not as a temporary makeshift.

Measures Against the Propaganda for the Prevention of Conception

The criminal court of the Seine has just condemned a certain Lip Tay, who has two advertisements with reference to the prevention of conception in a catalogue of special publications. Lip Tay's defense was that he was simply popularizing medical information. The court, however, did not sustain his plea and condemned him to pay $40 fine (200 francs) on the ground that this propaganda was an offense against morals. This decision will tend to arrest the propaganda.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Feb. 2, 1911.

Personal

Professor Ehrlich is the only medical trustee on the board of the newly founded Kaiser Wilhelm Society for Scientific Research (Gesellschaft für Förderung der Wissenschaften), half of whose members are elected by the society and the other half appointed by the Kaiser.

Professor Roentgen of Münich, Professor Hering of Leipsic, and Professor Retzius of Stockholm have received membership in the order of science and arts (Orden pour le Mérite der Wissenschaften und Künste), one of the few among the numerous Prussian orders which is bestowed *only for actual* achievement.

Professor Bier, director of the surgical clinic at Berlin, has been elected a foreign member of the Belgian academy of sciences.

Honorary Title for the Kaiser

The promotion of the Kaiser to the honorary title of Doctor by the Prague medical faculty will take place soon in the throne room of the palace in Berlin. The rector of the Prague German university, the present dean of the medical faculty, Professor v. Jaksch and Professor Hering will come to Berlin to officiate.

Multiple Offices for Physicians

In Berlin and probably also in other large cities of Germany it has been for some time the custom for a number of specialists to have offices for private patients in two places in the city, one in their private residence and one in their private clinic or the policlinic. The first is usually in the fashionable western part of the city and the latter in the center or in the outskirts. The reason for this condition is that the central part of Berlin, like London and New York, is gradually being given up more and more to business, for which reason the larger part of patients able to pay have migrated to the west and the physicians follow them but keep their office down town for the patients who still remain in that locality. As other physicians are injured by this doubling of offices there have been complaints made against this custom in the medical press and in the medical societies. As a result the business committee of the Berlin Medical Society, a short time ago, took up the question and made the following decision:

1. Policlinics in their essence and their historical development are institutions for the gratuitous treatment of the section of the public which is unable to pay. In addition to this humanitarian purpose they should serve the scientific and technical education of the physicians in charge, their assistants and other physicians. The gratuitous treatment of members of the Krankenkassen in the policlinics, dispensaries and the offices of the insurance physicians, has led, under the influence of the social legislation, to a deviation from the principal aim of gratuitous treatment. A further conversion of the policlinic and similar institutions into additional offices in which private patients are treated for pay, is as a whole contrary to the interests of special practice and of the medical profession.

2. The need for several offices for a physician doing a general practice does not exist to an extent to justify a deviation from the method in which medical practice has hitherto been carried on.

3. The decision as to whether in individual cases the maintenance of several offices for pay patients is permissible or not belongs only to the state medical court of honor.

Athletics at the Berlin University

The senate of the Berlin university has now acceded to a long-cherished wish of the university circles interested in gymnastics and sport by appointing, on motion of the university turner society, an academic committee which is to be the highest authority on all questions which concern physical exercise. The committee consists of the rector, Professor Rubner, Professor Waldeyer, Professor N. du Bois-Reymond, and others. The Berlin university in adopting this thoroughly modern arrangement which gives expression to the idea that the university should care not alone for the intellectual but also for the physical education of its youth is following the example of Breslau and Marburg. It now will be the task of the student body to show an interest in the matter corresponding to that of the authorities.

VIENNA LETTER

(From Our Regular Correspondent)

Vienna, Feb. 3, 1911.

Expenditures for the Medical Schools

The ordinary budget for medical teaching in Austria has a few days ago been finally fixed, and the figures are now published. For this purpose 6,000,000 kronen ($1,200,000) will be spent. Of this sum, Vienna receives 2,154,000 kronen ($430,800); Graz requires only 625,000 kronen ($125,000); Innsbruck 453,000 kronen; Prague, which has two medical schools, a German and a Slavic one, requires for each about 740,000 *kronen* or $150,000. Besides there are two Polish medical schools, one in Lemberg, requiring 480,000 kronen or $96,000, and one in Cracow, which receives $150,000. These sums cover only the ordinary expenditure; the sum of $50,000 is devoted to extraordinary expenses. Apart from these figures, the fees and salaries for special subventions and rewards amount to another $360,000. There are active at present:

	Vienna.	Prague.	Graz.	Innsbruck.	Lemberg.	Cracow.	Total.
Ordinary professors	25	31	14	15	14	15	114
Extraordinary professors	14	25	4	4	3	8	58
Assistants	86	85	37	31	34	38	311
Second-class assistants	6	6	1	2	0	1	16
	131	147	56	52	51	62	

The rent paid for certain of the medical university buildings amounts to over a million kronen, showing an increase of 15 per cent. since last year. The endowment of the institutions with grants and other sums for teaching material reaches more than double that sum. There are also certain paid lectures not strictly belonging to the medical teaching (photography, physical experimentation) which will cost 50,000 kronen ($10,000), and a sum of 100,000 kronen ($20,000) has been set apart for traveling grants (for researches).

The Austrian Antimalaria Campaign 1906-1909

The prevalence of malaria in certain parts of the Austrian coastland has prompted the government to institute a systematic campaign against the spread of this disease there. The official report states that in the first year 5,387 persons were examined, of whom 1,256, or 23 per cent., were found needy of treatment. In 1907, 3,192 persons were examined, 42 per cent. of this number were requiring antimalarial treatment. In one district fully 100 per cent. of the population were infected, while the lowest figure was 12 per cent. According to the instructions, in the endangered zone also persons who were not infected, but exposed to infection, were treated prophylactically. In the year 1909, only 3,351 more persons were examined. Of these, only 7 per cent. were found infected, whilst 1,848 (55 per cent.) received prophylactic treatment. In 1907, the districts examined contained 1,038 infected persons out of a population of 2,497, or 41 per cent., while another 384 persons presented themselves for prophylactic treatment. This was always free of charge, and consisted in administration of quinin sulphate in doses of 5 grains, together with arsenic and iron. From the examined districts, which have been under control since 1903 till 1908, every case of fever had to be reported and then examined for malaria. Out of a population of 18,774, 663 fresh infections were reported in these six years. As the people became persuaded of the benefit obtained from the regular treatment and persistence of control, the patients came in more regularly and finally there was no trouble at all, though at first some difficulty was experienced in inducing the uneducated peasants to submit to medical supervision.

Marriages

Milton M. Spitz, M.D., to Miss Belle Landau, both of Milwaukee, Wis., February 7.

J Dallas Croom, Jr., M.D. Maxton, N. C., to Miss Ruth Roberts of Attalla, Ala., recently.

Laurence Frank Keith, M.D., to Miss Elsie May Turner, both of Melrose, Mass., February 15.

John C. Bullitt, M.D., to Miss Edna Dever, both of Philadelphia, at Bingham, Mass., recently.

Alonzo J. Fitzporter, M.D., St. Louis, to Miss Marie Wanda Krebs of Belleville, Ill., February 8.

Alanson Halden Jones, M.D., Los Angeles, to Miss Adele Stookey of Hermosa Beach, Cal., January 31.

George E. Thompson, M.D., Kenosha, Wis., to Mrs. Anna Grun Lindstedt of Manitowoc, Wis., February 2.

William Schneider Shirk, M.D., Kansas City, Mo., to Miss Mary Gertrude McCourt of McPherson, Kan., at Kansas City, February 2.

Deaths

Joseph Rowe Smith, Brigadier General Medical Corps, U. S. Army, retired, died at the home of his sister in Philadelphia, February 11, from pneumonia, aged 79. He was graduated from the University of Buffalo, N. Y., in 1853, and a year later was commissioned as assistant surgeon in the army; five years later he was promoted to captain, and served in the west and southwest until the outbreak of the Civil War. When on duty at San Antonio, Tex., he was captured by the Confederates; and on being paroled was assigned to the duty of organizing hospitals. In 1862, he received his promotion to major, and at the close of the war was medical director of the Seventh Army Corps, and had been brevetted lieutenant colonel for "superior ability and excellent management of the affairs of the department." He was promoted to lieutenant colonel in 1885, attained his colonelcy in 1890; was retired by operation of law in 1895, and attained the rank of brigadier general, retired, nine years later. His last official duty was as medical director of the Department of the East. He was a member of the American Medical Association for many years, and vice-president in 1877, and was the Army delegate to the Association from 1874 to 1878, inclusive, and from 1882 to 1885, inclusive. He was also a delegate to four international medical congresses. General Smith was the author of a number of standard medical works, bearing particularly on the care and treatment of soldiers. He was one of the incorporators of the New York Post-Graduate Medical School and Hospital, and a member of the Association of Military Surgeons of the United States, American Academy of Medicine and many other medical societies.

Uranus Owen Brackett Wingate, M.D., for several years health commissioner of Milwaukee, and for ten years secretary of the Wisconsin State Board of Health; died at his home in Milwaukee, February 19, from pneumonia, aged 62. He was born in Rochester, N. H., enlisted in the Army at the age of 16 and served throughout the Civil War. He attended three courses of lectures at Harvard Medical School, and Dartmouth Medical School, Hanover, N. H., graduating from the latter institution in 1875. He practiced until 1886 in Haverhill and Wellesley, Mass., and served for five years as a member of the Medical Corps of the Massachusetts Volunteer Militia. In 1886, he moved to Milwaukee, four years later was made health commissioner of the city, and 1894, was appointed secretary of the Wisconsin State Board of Health. He was a member of the American Medical Association, and for several years chairman of the committee on the national department of health; the American Public Health Association, American Psychological Association, and the Milwaukee County Medical Society, of which he was once president. He was professor of diseases of the nervous system and hygiene in the Wisconsin College of Physicians and Surgeons; visiting neurologist to St. Mary's and Milwaukee County Hospitals, and consulting neurologist to St. Joseph's Hospital. He contributed many articles on subjects connected with his specialties, to the medical literature.

Horace Wilbur Patterson, M.D. College of Physicians and Surgeons, New York City, 1895; a member of the Medical Society of the State of New York; and for five years secretary of the Richmond County Medical Society; chief of the department of communicable diseases of the Department of Health of Richmond Borough, and pathologist to the S. R. Smith Infirmary; assistant surgeon of the First New Jersey Infantry, U. S. V., during the Spanish-American War, and afterwards captain and assistant surgeon of the First Infantry, N. J. National Guard, and First Lieutenant Medical Reserve Corps, U. S. Army; died in the S. R. Smith Infirmary, February 5, after an operation for cholelithiasis, aged 38.

James Kerr, M.D. Queen's University, Dublin, Ire., 1870; a member of the Medical Association of the District of Columbia; professor of surgery in Georgetown University, and a member of the surgical staff of Providence and Emergency Hospitals and the Woman's Dispensary; surgeon in the British service during the Ashanti war; later chief surgeon of the Canadian Pacific Railway; surgeon in the Canadian militia; one of the organizers of, and president and professor of surgery in the Manitoba Medical College, Winnipeg; since 1888 a resident of Washington, D. C.; died at his country home near Warrenton, Va., February 2, aged 62.

Samuel David Hopkins, M.D. University of Pennsylvania, Philadelphia, 1893; a member of the American Medical Association, and American Neurological Society; professor of nervous and mental diseases in the Denver College of Medicine and Surgery; president of the staff of St. Joseph's Hospital, and neurologist to Denver County Hospital; a specialist on nervous and mental diseases; died in St. Joseph's Hospital, Denver, February 4, two days after an operation for appendicitis, aged 38. At a special meeting of the City and County of Denver, resolutions were adopted eulogizing the character, work and personality of Dr. Hopkins.

Joseph B. Ward, M.D. Hahnemann Medical College, Philadelphia, 1857; at one time professor in the Homeopathic Medical College of Missouri, St. Louis; assistant surgeon of the Eleventh New York Volunteer Infantry during the Civil War; for two years vice-president of the New Jersey Tuberculosis Commission; chairman of the executive committee of the State Horticultural Society; a member of the executive committee of the State Board of Agriculture; died at his home in Newark, February 3, from heart disease, aged 76.

James Buchanan Walker, M.D. Miami Medical College, Cincinnati, 1882; local surgeon at Effingham, Ill., of the Illinois Central, Vandalia, and Wabash Railways; a member of the surgical staff of St. Anthony's Hospital; a member of the American Medical Association, and Æsculapian Society of the Wabash Valley, and American Association of Life Insurance Examiners; supreme medical examiner of the fraternal order of Modern Americans; died at his home, February 11, from cerebral hemorrhage, aged 54.

Edwin Powell, M.D. Rush Medical College, Chicago, 1857; formerly demonstrator of anatomy and professor of military surgery in his alma mater; surgeon of the Seventy-Second Illinois Volunteer Infantry, and later in charge of the Seventeenth Army Corps Hospital and the McPherson General Hospital during the Civil War; a member of the staff of Cook County Hospital; died at his home near Maryville, Mo., February 13, from influenza, aged 76.

Edwin Gilmore Knill, M.D. University of Toronto, 1882; M.R.C.S., Eng., L.R.C.P., Lond., 1883; L.R.C.S., L.R.C.P., Edin., 1883; a member of the Michigan State Medical Society; adjunct professor of pathology and morbid anatomy, and clinical professor of medicine in the Detroit College of Medicine; a member of the staff of Harper Hospital; died at his home in Detroit, February 10, from cerebral hemorrhage, aged 55.

Columbus Henry, M.D. University of Pennsylvania, Philadelphia, 1871; formerly a member of the Delaware State Medical Society and State Board of Medical Examiners; for many years president of the Board of Trustees of the Poor of Newark, Del., and president of the Board of Trustees of the Newcastle County Hospital; died at his home in Newark, January 14, from hepatic and arteriosclerosis, aged 67.

Frank S. Low, M.D. Castleton (Vt.) Medical College, 1850; once president of the Oswego County Medical Society and vice-president of the Medical Society of the State of New York; consulting physician to the Oswego City Hospital; once sheriff and coroner of Oswego County, N. Y.; a member of the board of education; died at his home in Pulaski, February 3, aged 82.

Reuben Conway Shultz, M.D. New York University, New York City, 1880; a member of the Medical Society of the State of California; for several years a member of the staff of the *New York Medical Journal,* but for the last thirteen years a resident of Los Angeles; died at his home in that city, January 29, from chronic bronchitis, aged 57.

Syndicat des stations thermales de France, which is directly interested in the question, has undertaken to provide the expense of the chair. The only condition imposed by the *syndicat* on its gift is that the professor appointed shall be competent, and shall promise to regard the position as permanent, not as a temporary makeshift.

Measures Against the Propaganda for the Prevention of Conception

The criminal court of the Seine has just condemned a certain Lip Tay, who has two advertisements with reference to the prevention of conception in a catalogue of special publications. Lip Tay's defense was that he was simply popularizing medical information. The court, however, did not sustain his plea and condemned him to pay $40 fine (200 francs) on the ground that this propaganda was an offense against morals. This decision will tend to arrest the propaganda.

James Kerr, M.D. Queen's University, Dublin, Ire., 1870; a member of the Medical Association of the District of Columbia; professor of surgery in Georgetown University, and a member of the surgical staff of Providence and Emergency Hospitals and the Woman's Dispensary; surgeon in the British service during the Ashanti war; later chief surgeon of the Canadian Pacific Railway; surgeon in the Canadian militia; one of the organizers of, and president and professor of surgery in the Manitoba Medical College, Winnipeg; since 1888 a resident of Washington, D. C.; died at his country home near Warrenton, Va., February 2, aged 62.

Samuel David Hopkins, M.D. University of Pennsylvania, Philadelphia, 1893; a member of the American Medical Association, and American Neurological Society; professor of nervous and mental diseases in the Denver College of Medicine and Surgery; president of the staff of St. Joseph's Hospital, and neurologist to Denver County Hospital; a specialist on nervous and mental diseases; died in St. Joseph's Hospital, Denver, February 4, two days after an operation for appendicitis, aged 38. At a special meeting of the City and County of Denver, resolutions were adopted eulogizing the character, work and personality of Dr. Hopkins.

Joseph B. Ward, M.D. Hahnemann Medical College, Philadelphia, 1857; at one time professor in the Homeopathic Medical College of Missouri, St. Louis; assistant surgeon of the Eleventh New York Volunteer Infantry during the Civil War; for two years vice-president of the New Jersey Tuberculosis Commission; chairman of the executive committee of the State Horticultural Society; a member of the executive committee of the State Board of Agriculture; died at his home in Newark, February 3, from heart disease, aged 76.

James Buchanan Walker, M.D. Miami Medical College, Cincinnati, 1882; local surgeon at Effingham, Ill., of the Illinois Central, Vandalia, and Wabash Railways; a member of the surgical staff of St. Anthony's Hospital; a member of the American Medical Association, and Æsculapian Society of the Wabash Valley, and American Association of Life Insurance Examiners; supreme medical examiner of the fraternal order of Modern Americans; died at his home, February 11, from cerebral hemorrhage, aged 54.

Edwin Powell, M.D. Rush Medical College, Chicago, 1857; formerly demonstrator of anatomy and professor of military surgery in his alma mater; surgeon of the Seventy-Second Illinois Volunteer Infantry, and later in charge of the Seventeenth Army Corps Hospital and the McPherson General Hospital during the Civil War; a member of the staff of Cook County Hospital; died at his home near Maryville, Mo., February 13, from influenza, aged 76.

Edwin Gilmore Knill, M.D. University of Toronto, 1882; M.R.C.S., Eng., L.R.C.P., Lond., 1883; L.R.C.S., L.R.C.P., Edin., 1883; a member of the Michigan State Medical Society; adjunct professor of pathology and morbid anatomy, and clinical professor of medicine in the Detroit College of Medicine; a member of the staff of Harper Hospital; died at his home in Detroit, February 10, from cerebral hemorrhage, aged 55.

Columbus Henry, M.D. University of Pennsylvania, Philadelphia, 1871; formerly a member of the Delaware State Medical Society and State Board of Medical Examiners; for many years president of the Board of Trustees of the Poor of Newark, Del., and president of the Board of Trustees of the Newcastle County Hospital; died at his home in Newark, January 14, from hepatic and arteriosclerosis, aged 67.

Frank S. Low, M.D. Castleton (Vt.) Medical College, 1850; once president of the Oswego County Medical Society and vice-president of the Medical Society of the State of New York; consulting physician to the Oswego City Hospital; once sheriff and coroner of Oswego County, N. Y.; a member of the board of education; died at his home in Pulaski, February 3, aged 82.

Reuben Conway Shultz, M.D. New York University, New York City, 1880; a member of the Medical Society of the State of California; for several years a member of the staff of the *New York Medical Journal*, but for the last thirteen years a resident of Los Angeles; died at his home in that city, January 29, from chronic bronchitis, aged 57.

Carter Lurton Broaddus, M.D. Vanderbilt University, Nashville, Tenn., 1892; a member of the Kentucky State Medical Society, and formerly vice-president of the Trigg County (Ky.) Medical Society; for many years a resident of Hopkinsville; died in Lebanon, Tenn., January 11, from cerebral hemorrhage, aged 48.

Riley Allen Atkins, M.D. Medical College of Virginia, Richmond, 1864; a member of the Newport News Medical Society; a sailor in the Confederate navy during the Civil War, detailed to hospital duty; surgeon for the Virginia Railway at Pine Beach; died at his home, January 9, from pneumonia, aged 74.

Walter Howard Snow, M.D. New York University, New York City, 1880; formerly physician to the Society for the Prevention of Cruelty to Children, and instructor in gynecology in the University of the City of New York; died at his home in New Lebanon, N. Y., January 27, from uremia, aged 51.

Joseph Clements, M.D. Kansas City (Mo.) Medical College, 1891; and later clinical instructor on diseases of children in his alma mater; for twenty years a clergyman; a writer on psychology and metaphysics; died at his home in Wichita, Kan., January 31, from valvular heart disease, aged 70.

John Cassilis Cockburn, M.D. Harvard Medical School, 1872; a member of the American Medical Association; once president of the Hennepin County Medical Society; for thirty-one years a practitioner of Minneapolis; died at his home in that city, February 5, from interstitial nephritis, aged 69.

Jane Howell Harris, M.D. Woman's Medical College of the New York Infirmary for Women and Children, 1899; for eight years a medical missionary of the Presbyterian Board in San Juan, Porto Rico; died at her home in Isabela, Porto Rico, Nov. 21, 1910, from pneumonia, aged 38.

William Menger, M.D. New York University, New York City, 1897; of Union Hill, N. J.; while suffering from mental disorder and an inmate of a sanitarium at Paterson, N. J., is said to have cut his throat, January 8, inflicting a wound from which he died soon after, aged 34.

Hubert Pemberton Doak, M.D. University of Nashville, Tenn., 1893; a member of the Tennessee State Medical Association; formerly of Greenville, and secretary of the local pension examining board; died at his home in Tusculum, February 5, from pneumonia, aged 46.

Augustine von Galny, M.D. University of Berlin, Germany, 1847; (license, Eighteenth Judicial District Board, Texas,, 1878); surgeon in the Prussian and Danish armies; a member of the State Medical Association of Texas; died at his home in Galveston, February 1, aged 83.

George W. Menees, M.D. Vanderbilt University, Nashville, 1879; a member of the Missouri State Medical Association; health officer of Clinton; died February 7, from the inhalation of fumes of formaldehyd, after disinfecting a house where small-pox had occurred, aged 54.

Joseph Preston Gray, M.D. University of Tennessee, Nashville; a graduate in both medicine and dentistry; a member of the American Medical Association; and of the Nashville Academy of Medicine; died at his home, Sept. 30, 1910, from cerebral hemorrhage, aged 55.

John Warner Kniskern, M.D. Albany (N. Y.) Medical College, 1890; ophthalmic and aural surgeon to the Amsterdam (N. Y.) Hospital; a specialist in diseases of the eye and ear; died at his home in Amsterdam, January 31, from tuberculosis of the throat, aged 43.

Alexander McKlveen McLain, M.D. Western Pennsylvania Medical College, Pittsburg, 1898; of Post Falls, Ida., formerly of Irwin Pa.; for two years a member of the village council; died in Spokane, Wash., January 12, from pernicious anemia, aged 51.

James A. C. Milliken, M.D. Medical School of Maine, Brunswick, 1910; assistant in the Western Washington Hospital for the Insane, Fort Steilacoom; died at his home in New Bedford, Mass., Dec. 29, 1910, from lymphatic leukemia, aged 25.

George Augustus Steinicken, M.D. University of Pennsylvania, Philadelphia, 1890; of New York City; until 1904 a practitioner of Wilmington, Del.; died in Roosevelt Hospital, New York City, Dec. 22, 1910, from pneumonia, aged 45.

Alfred Augustus Herrmann, M.D. College of Physicians and Surgeons, Chicago, 1904; of Chicago; a member of the American Medical Association; died in Pasadena, Cal., Nov. 29, 1910, from tuberculosis of the kidney, aged 30.

John Kapp, M.D. University of Michigan, Ann Arbor, 1868; a member of the Michigan State Medical Society; for three terms mayor of Ann Arbor; died at his home in Los Angeles, January 17, from general breakdown, aged 69.

Benjamin W. Searle, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1873; of Ottumwa, Ia.; a veteran of the Civil War; died in Wesley Hospital, Chicago, February 17, after an operation for appendicitis, aged 69.

Leroy Hall Sibley, M.D. College of Physicians and Surgeons, Chicago, 1903; a member of the Vigo County (Ind.) Medical Society; died at his home in Terre Haute, Sept. 26, 1910, from pulmonary tuberculosis, aged 30.

Leroy W. Heath, M.D. Cleveland University of Medicine, and Surgery, 1882; a member of the Medical Society of the State of Pennsylvania; died at his home in Mercer, Pa., January 26, from general paresis, aged 52.

Cyrenius Benjamin Vaughan, M.D. Bellevue Hospital Medical College, 1875; a member of the Medical Society of the State of New York; died at his home in Morrisonville, February 1, from heart disease, aged 64.

Louis deValois Wilder, M.D. Hahnemann Medical College, Philadelphia, 1855; for many years chief surgeon of the Flower Hospital; died at his home in New York City, February 5, from heart disease, aged 93.

James Marshall Tinsley, M.D. University of Louisville, Ky., 1880; formerly of Champaign, Philo and Rantoul, Ill.; died at his home in Mount Vernon, Ill., February 2, from cerebral hemorrhage, aged 61.

Leo J. O'Shaughnessy, M.D. Kansas City (Mo.) Hahnemann Medical College, 1908; was shot and killed in a pistol duel with a brother physician, in his office in Wetumka, Okla., February 3, aged 28.

Richard Maury Cunningham, M.D. Vanderbilt University, Nashville, 1892; for thirty-three years a practitioner of Tennessee; died at his home in Palmyra, Nov. 25, 1910, from pneumonia, aged 74.

Frank H. Fisk, M.D. Albany (N. Y.) Medical College, 1883; a member of the Medical Society of the State of New York; died at his home in West Sand Lake, January 22, from lobar pneumonia, aged 56.

Edward Francis Dodd, M.D. University of Nebraska, Lincoln, 1887; for twenty years a practitioner of Newport, Neb.; died at Fairview, Okla., Dec. 29, 1910, from edema of the glottis, aged 47.

Isaac Francis Coffin, M.D. New York University, New York City, 1885; coroner of Herkimer County, N. Y., in 1900; died at his home in North Ilion, Dec. 23, 1910, from spinal disease, aged 62.

Charles Eugene Arthur Dorval, M.D. Victoria College, Coburg, Ont., 1874; of Montreal; died in the Hôtel Dieu in that city, Dec. 26, 1910, from peritonitis, following a gastric ulcer, aged 58.

Lawrence Ryan, M.D. Dublin (Ire.) Medical College; at one time medical health officer of Edmonton, Alta.; died in Saskatoon, Sask., Nov. 10, 1910, from heart disease complicating typhoid fever.

Alfred Wesley Bear, M.D. Washington University, Baltimore; for nearly forty years a practitioner of Barnard, Mo.; died at his home in that place, January 21, from influenza, aged 69.

Felix Dydine Fontaine, M.D. Laval University, Montreal, 1857; (license, Massachusetts, years of practice, 1894); died at his home in Worcester, January 31, from senile debility, aged 79.

Henry Rutgers Cannon, M.D. New York University, New York City, 1843; first clerk of Union County, N. J.; died at his home in Elizabeth, January 9, from senile debility, aged 89.

Lincoln D. Foreman, M.D. American Medical College, Eclectic, St. Louis, 1884; slipped from a ladder at his home in Peoria, Ill., February 9, and was instantly killed, aged 49.

Seth H. Truesdale, M.D. Western Reserve University, Cleveland, 1876; a veteran of the Civil War; died at his home in Poland, O., February 5, from locomotor ataxia, aged 69.

George W. Ray, M.D. Rush Medical College, 1867; a pioneer practitioner of Joplin, Mo.; died at St. John's Hospital in that city, February 8, from pernicious anemia, aged 68.

George W. Corman, M.D. American Medical College, Eclectic, St. Louis, 1883; of Paris, Ark.; died on a train near Lavaca, Ark., Dec. 15, 1910, from heart disease, aged 54.

Thomas Graham, M.D. Grand Rapids (Mich.) Medical College, 1907; died at his home in St. James, Beaver Island, Mich., January 16, from diabetes, aged 34.

Lawrence Ellsworth Jones, M.D. Howard University, Washington, D. C., 1907; died at his home in Rochester, Pa., Dec. 28, 1910, from acute nephritis, aged 31.

F. C. Woodard, M.D. Louisville (Ky.) Medical College, 1887; a member of the American Medical Association; died at his home in Grapeland, Tex., January 31, aged 63.

James Arthur Metcalfe, M.D. Louisville (Ky.) Medical College, 1873; died at his home in Los Angeles, Cal., January 18, from carcinoma of the leg, aged 58.

Evan Jones, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1876; died at his home in New Cambria, Mo., January 30, from pneumonia, aged 65.

John C. David, M.D. Hahnemann Medical College, Chicago, 1878; died at his home in Sandwich, Ill., February 2, from cancer of the esophagus, aged 62.

J. W. Bartlett (license, Kentucky, thirty-six years of practice, 1893); died at his home in Kirkmansville, February 8, from senile debility, aged 78.

Theodore Rahlfs, M.D. Rush Medical College, 1888; died in his office in Tacoma, Wash., January 23, in an epileptic convulsion, aged about 60.

George Fisk Wilber, M.D. Long Island College Hospital, Brooklyn, 1864; died at his home in Nashua, N. H., January 21, aged 71.

Association News

THE LOS ANGELES SESSION

Arrangements Being Perfected for the Next Annual Session

Readers of The Journal will be kept informed from week to week concerning the arrangements for the Los Angeles Session. In the last issue, a list of hotels was published, giving the rates, capacities, etc., and a preliminary announcement of the railroad rates; and this week there is given some information about special trains and entertainments.

Entertainments

The Los Angeles Session bids fair to stand out with unusual prominence with respect to the amount and quality of entertaining done by the local profession. The matter is spoken of thus early to encourage members to plan to go to Los Angeles. The occasion will be one of great enjoyment. Some of the entertainments are as follows: On Friday those who have finished their section work will be taken by boat to the famous Catalina Island and given a barbecue. This trip will be duplicated on Saturday for the others in attendance.

Friday will also be called Pasadena Day. Shortly after noon, when all the scientific work will have been completed, there will be an automobile trip to Pasadena with a Spanish barbecue in the Sunken Gardens. This will be followed by chariot races in Tournament Park, especially arranged for the benefit of the members of the American Medical Association. The day will be concluded by trips to the seashore with entertainments at Venice and Ocean Park.

On Saturday those who do not wish to go to Catalina Island may take a trip to San Pedro Harbor and Long Beach with lunch at the Hotel Virginia.

Other trips in the vicinity, for which especial railroad rates will probably be granted, are to the olive orchards of San Fernando, to the orange groves of Riverside and Redlands and to San Diego, the renowned resort some miles down the coast.

Judging from the inquiries received by various committees, the attendance at Los Angeles will probably be larger than a good many prophets anticipated, who were judging solely by the distance of the meeting-place from the center of the United States. The attractiveness of Los Angeles and the opportunity of various trips are two things which will largely tend to counteract the distance. For this reason we repeat the suggestion of last week, given in connection with the list of hotels, and urge those who expect to go to Los Angeles that they reserve hotel accommodations early. There are plenty of hotels, but those who write for accommodations late cannot expect to have their choice of the best rooms.

Announcement of Transportation Committee

In looking over the numerous letters of the members received in response to the request published in The Journal, Dec. 10, 1910, p. 2078, it is found that a large majority of them are in favor of taking the southern route to Los Angeles in June. The committee therefore announces that it has arranged for a special train from Chicago to Los Angeles over the Santa Fé route. This train, which will be a counterpart of the famous California Limited, will afford every first-class accommodation, standard berths, compartments and drawing-rooms. There will be a fully equipped club car with valet and barber in attendance, dining car and observation car. The club car and observation parlor are supplied with an abundance of the best current magazines and newspapers, a carefully selected library and writing material.

This train will leave Chicago at 8:00 p. m., Wednesday, June 21, and will run in accordance with the following schedule:

TIME SCHEDULE OF SPECIAL TRAIN

Lv. Chicago	8:00 p. m.,	Wednesday,	June 21
Ar. Kansas City	9:00 a. m.,	Thursday,	June 22
Lv. Kansas City	9:10 a. m.,	Thursday,	June 22
Ar. Albuquerque	11:05 a. m.,	Friday,	June 23
Lv. Albuquerque	12:30 p. m.,	Friday,	June 23
Ar. Laguna	2:30 p. m.,	Friday,	June 23
Lv. Laguna	3:30 p. m.,	Friday,	June 23
Ar. Grand Canyon	6:00 a. m.,	Saturday,	June 24
Lv. Grand Canyon	10:00 a. m.,	Sunday,	June 25
Ar. Los Angeles	7:00 a. m.,	Monday,	June 26

At Albuquerque a stop of one hour and a half will be made in order to afford an opportunity for all to visit the very interesting collection of Indian and Mexican hand work. This is undoubtedly the finest collection of Indian and Mexican work in the world. At Laguna a stop of one hour will be made, affording an opportunity to visit the Pueblo Indian village. These short stops not only break the monotony of the trip but also permit of sight-seeing which cannot be had on any of the regular trains.

A stop of twenty-eight hours will be made at the Grand Canyon. It is unnecessary to dilate on the wonderful beauty of this work of Nature. The time spent here is sufficiently long to permit of descending into the canyon and also of visiting points of interest on the rim. Being there over night also affords an opportunity of seeing the sun rise and set. These sights alone are well worth the trip.

The train will arrive at Los Angeles at 7:00 o'clock Monday morning in time for the delegates to attend the opening meeting of the House of Delegates. For those members who do not care to reach Los Angeles before Monday evening, arrangements will be made whereby cars will be taken via Redlands and Riverside and sufficient time given to visit both these interesting points, reaching Los Angeles about 6:00 p. m.

The round trip fare from Chicago is $62.50 with an addition of $6.50 for the Grand Canyon side ride. The Pullman rates are, upper berth $12.80, lower berth $16.00, compartment $45.00, drawing-room $56.00. These rates include the side trip to the Grand Canyon and also provide for the occupancy of the cars at the Grand Canyon if so desired.

One may return by any direct route, which means by any route going as far north as San Francisco and Ogden. To those who wish to return by any of the northern routes, an additional fare of $15.00 will be charged. These rates are not available for both going and returning by the northern routes. All those, therefore, who contemplate visiting Yellowstone Park, the Canadian Rockies or other points of interest on the northern routes are cautioned to see that they go by some of the southern routes and arrange for these stop-overs on their return trip. There will be plenty of time to make all of these trips after the meeting on the return passage, as the return limit on the tickets is September 15, but there will not be time to make these extended side trips going.

Announcement of eastern rates and trains will be made later.

M. L. Harris, Chicago,
Chairman, Committee on Transportation.

REPORT OF THE COMMITTEE ON PHYSIOLOGIC ASSAY

Of the Philadelphia Branch of the American Pharmaceutical Association *

Dr. T. C. Githens, Dr. C. A. Hofer, Dr. John C. Scott, and Dr. H. C. Wood, Jr., Chairman

The Committee on Physiologic Assay of the Philadelphia Branch of the American Pharmaceutical Association has considered the advisability of introducing into the Pharmacopeia physiologic tests for the following drugs: apocynum, convallaria, digitalis, squill, strophanthus, aconite, gelsemium, lobelia, veratrum, cannabis, ergot, pepsin, suprarenals, thyroid, chenopodium, granatum, kousso, santonica, cimicifuga, gossypii cortex and phytolacca.

Cimicifuga, gossypii cortex and phytolacca seem of too little importance to require physiologic standardization.

The vermifuges—chenopodium, granatum, kousso and santonica—might, we believe, readily be standardized according to the method which was employed, in connection with the oil of chenopodium, by Brunning,[1] who determined the vermicidal effect on the intestinal worms obtained from the alimentary tract of dogs and cats. Inasmuch, however, as we are unaware of any application of this method for the purpose of standardization and as time was insufficient for experimental work on the part of the committee, we do not feel inclined to recommend the introduction of physiologic tests in connection with these drugs, although we would call the attention of the Committee on Revision of the Pharmacopeia to the possibility of such standardization.

Cannabis.—Two standards have been suggested for cannabis indica. That which is most frequently employed is the amount which is required to produce muscular incoordination in the dog. The other is the amount required to produce narcosis in the frog. As regards the second of these tests, the fact that cannabis indica is practically insoluble in water and that frogs are very susceptible to the action of alcohol seems to us to preclude its use. In regard to the first test, it has been the universal experience that there is a large variation in individual susceptibility in different dogs, so that to obtain results which are even approximately accurate it is necessary to use the same dog repeatedly. The prolonged use of the drug, however, appears to beget a certain amount of immunity toward it, so that one dog can be used for only a comparatively small number of tests. Even with the utmost precautions, the results are far from accurate. As it is impossible, on account of individual idiosyncrasies and the uncertainty of the final reaction, definitely to assign any dose and as the results are so inaccurate, we feel that until some more satisfactory means of standardizing cannabis indica has been suggested, no physiologic assay process should be introduced into the Pharmacopeia.

Ergot.—Another drug which urgently requires some method of standardization is ergot. The cock's-comb test, as has been shown by Edmunds and in our own experiments, is unreliable. Two other methods have been suggested for this purpose: one based on the activity of the drug on uterine muscle, and the other based on its effects on the circulation. Each of these methods requires either that the sample be compared to a standard preparation, or else that a considerable series of animals be employed for each test, and the average taken of the series. Against the method of comparing the effects with a standard preparation rises the almost insuperable obstacle of keeping a standard preparation on hand without deterioration. Our opposition, expressed in connection with digitalis, to any method of test for any drug which requires comparison with a standard preparation which cannot be made by any competent pharmaceutical chemist, applies still more strongly to ergot. The method of taking the average of a series makes the assay so expensive and so tedious as practically to preclude its use by any but the largest wholesale manufacturers. Moreover, there is at least a reason to hope that before the next edition of the Pharmacopeia appears, a satisfactory chemical test for this drug will have been devised. For these reasons we do not recommend the introduction of a physiologic standard for ergot.

Thyroid.—Thyroid gland does not in our opinion require physiologic standardization, as the work of Hunt has shown that the percentage of combined iodin is an accurate indicator of the quality of the drug, and we believe that wherever a chemical test is equally available it should be given the preference to a physiologic one.

Veratrum.—The one physiologic test for veratrum which, so far as our reading goes, has been suggested, is the quantity required to kill. As this substance contains a number of alkaloids which are quite different in their effect, we do not believe that such a test is of any great practical importance. Moreover, as the active principle of this drug is alkaloidal in nature, it would appear to us that a method of chemical standardization could be devised. We would call attention to the fact, however, that the total percentage of alkaloid is no indication of physiologic power of the drug, for, as has been shown by Eden,[2] the protoveratrin, which constitutes a comparatively small percentage of the alkaloidal content of the plant, is so much more powerful than any other principle that it practically dominates the action of the drug.

Aconite.—Although the Pharmacopeia directs that aconite should contain 0.5 per cent. of aconitin, yet the method described gives rather the total alkaloids of the drugs. The percentage of total alkaloids is by no means an accurate criterion of the activity of the specimen, since there are present in the crude drug at least two other alkaloids besides aconitin, which are greatly inferior in potency; therefore, the drug might assay comparatively high in alkaloid, but be of feeble physiologic power. We would recommend, therefore, the introduction of a physiologic standard for this remedy. E. R. Squibb suggested a method of physiologic standardization based on the power of aconite to cause tingling of the lips. A definite amount of the drug is rubbed with 1 c.c. of water and held in the mouth for one minute. This should cause a tingling of the lips, coming on in about twenty minutes and lasting about an hour. This test is unreliable, both because of the difference in susceptibility of different persons and because of the great variations in the susceptibility of the same individual on different days. The standard which we would suggest is based on the amount required to kill a given weight of animal within a period of twenty-four hours. The fact that guinea-pigs may be readily obtained and are so easily handled makes them the most available animals for this purpose.

We suggest the following standard:

> Aconite should be of such strength that it requires not less than 0.4 mg. or more than 0.5 mg. per gram of body weight to kill a guinea-pig when tested in the following manner:
>
> From the specimen to be tested, a fluidextract is made according to the official process. Four guinea-pigs are then carefully weighed and into two of them is injected beneath the skin of the abdomen an equivalent of 0.0004 gm. of aconite for each gram of the body weight, and into the other two is injected 0.0005 gm. per gram of body weight. If at the end of twelve hours the first two survive and the second two are dead, the drug is of satisfactory quality. If the first two die, it is too strong; if the second two survive, it is too weak. If one of either pair lives and the other dies, the test must be repeated.

Digitalis Group.—Apocynum, convallaria, digitalis, scilla and strophanthus are placed together by pharmacologists, as they have much the same physiologic actions. As there is no satisfactory method of chemical standardization for any of these drugs, the committee feels that the adoption of a physiologic method of assay would be advisable.

---

* Read before Scientific Section of the Philadelphia Branch of the American Pharmaceutical Association, Nov. 10, 1910.

[1] Brunning: Ztschr. f. exper. Pharm. u. Therap., 1905, L, 80.

[2] Eden: Arch. f. exper. Path., xxix, 40.

Three types of test have been suggested for the standardization of these drugs: (1) the dose required to kill a warm-blooded animal, as the guinea-pig; (2) the amount required to produce the arrest of the heart of a frog in a given period of time; (3) the degree of elevation of blood-pressure in a warm-blooded animal. The last of these methods may be immediately excluded as being the least reliable of the three, and also the most complex technically. Concerning the choice between the first two methods, while recognizing that there are valid arguments in favor of each, we are inclined to prefer the test on the guinea-pig. It is true that in the study of Edmunds and Hale[3] the frog test appeared to be somewhat more accurate, showing in no case an error of more than 10 per cent. There are, however, two serious objections to the frog method as an official process of assay. In all of these frog tests a time limit has been given, and the various time limits have ranged from one to twenty-four hours. According to the author just quoted, the fatal dose for twelve hours is about three-fourths of that for one hour. It is evident that the difference between the dose required to kill in one hour and that required to kill in twelve hours is largely a question of the rapidity of absorption. Now it may easily be that a preparation which is highly active may, for some reason, be comparatively slowly absorbed, so that the one-hour test is not only of activity of the drug, but of absorbability, which manifestly is not the purpose of the assay.

Another objection which seems to us almost insurmountable is the great variation in the susceptibility of frogs. In the first place, it is a well-recognized fact that frogs of different species vary widely in their susceptibility to members of the digitalis group. It would, therefore, be essential to use always frogs of one species. This offers no trouble if the tests were to be carried out only in one part of the United States, but the species of frogs which are common in Maine are not found at all in California. The most widely distributed frog, the *Rana pipiens*, does not occur west of the Sierra Nevada. Not only do frogs of different species show variations in their susceptibility, but it is recognized that the season of the year influences this. According to a statement made by Dr. Hale in a discussion of this subject before the Philadelphia Branch of the American Pharmaceutical Association, this difference is due simply to the effects of temperature and can be overcome by working always in a room of certain temperature. We are not familiar, however, with any experimental proof of this statement, and it seems, *a priori*, improbable. Moreover, there is reason to believe that even the same species of frog varies according to the locality from which it is obtained. Dr. Donaldson of the Wistar Institute of Anatomy has found a marked difference in the relation of total-body weight to the weight of the central nervous system in frogs of the same species, obtained from different parts of the country. While this does not, of course, absolutely prove that there would be a difference in the susceptibility to digitalis, it necessitates at least a careful study of the comparative susceptibility of frogs of the same species from different regions, before it can be taken for granted that they will be the same.

The only method of overcoming these obstacles would seem to be by comparing the preparation tested with a standard preparation. We are convinced that such a method of standardization is undesirable for pharmacopeial purposes. It would necessitate a distribution either by the government or the Pharmacopeial Convention of a standard preparation, and although the experiments of Houghton indicate that tincture of strophanthus might be available for this purpose, such a standard would have to be tested almost continuously by the distributors and given out at comparatively short intervals. Chance deterioration in the standard might easily result in flooding the market with inferior preparations before the fact was discovered and corrected.

Guinea-pigs, on the other hand, are obtainable in all parts of the world. They are already used for standardization of various remedies, and their susceptibility to digitalis, so far as known, does not vary under ordinary conditions. Temperature, food, season, weight and sex do not influence their reaction. We therefore recommend the use of guinea-pigs for the determination of the physiologic activity of drugs of this group. As the methods of assay for all the members of this group are the same, we shall describe the test as applied to digitalis only.

> Digitalis should be of such strength that when tested in the following manner it shall require not less than 0.35 mg. or more than 0.40 mg. per gram of body weight to kill a guinea-pig in twelve hours.
>
> Method of Assay: From the sample to be tested a tincture shall be made according to the official process; four guinea-pigs are then carefully weighed, and into two of them an amount of the tincture corresponding to 0.35 mg. per grain of body weight is injected beneath the skin of the abdomen and into the other two a uantity equivalent to 0.40 mg. is injected. If both of the first pair survive and both of the last pair die, the drug is of satisfactory quality. If, however, both of the first pair die, the sample is too strong, or, if both of the second pair survive, too weak. If, of either pair, one survives and one dies, the test should be repeated.

Suprarenal.—If suprarenal glands remain official in the next revision of the Pharmacopeia, we believe that there should be some standard of strength introduced. As at present there is no chemical assay available, and as the physiologic test is one of the simplest of all pharmacologic experiments, we recommend the introduction of the following method for the physiologic assay of suprarenal glands.

> Suprarenal gland should be of such strength that 1 gm. injected intravenously into a dog shall produce a rise of mean blood-pressure within 10 mm. of that produced in the same animal by a dose of 0.001 gm. of the pure active principle when tested in the following manner:
>
> Method of Assay: A dog weighing between 5 and 15 kilograms is anesthetized by injecting hypodermically 0.08 gm. of morphin sulphate for each kilo of body weight, supplemented with the use of such quantity of ether as shall be necessary to prevent pain. One of the larger arteries, as the femoral or carotid, is then connected with a mercury manometer and the animal allowed to come from under the influence of the ether. No experiments should be begun until at least ten minutes have intervened after the withdrawal of the ether. At the end of this period, the normal pressure should be recorded for a period of at least ten minutes, and then a dose of 0.001 mg. of pure active principle for each kilo of body weight is injected intravenously and the blood-pressure observed for at least three minutes. At a period of not less than twenty minutes after the first injection, a dose of 1 mg. of the sample to be tested is injected in the same manner and the pressure observed again for ten minutes. Ten minutes after the injection of this sample a second dose of the pure active principle is to be injected. The elevation of the blood-pressure at the highest point reached after each injection above the pressure at the time the injection was made is then measured. The rise of blood-pressure which was produced by the second injection should be within 10 mm. of the average of the first and third injections.

MRS. PRICE'S CANNING COMPOUND

When the federal Food and Drugs Act went into effect, the use of certain chemical preservatives which had been proved injurious was prohibited in food-stuffs that entered into interstate commerce. One of these preservatives was boric acid. As the harmfulness of this chemical became generally known, housewives and others who had been in the habit of using it for preservative purposes abandoned it. It was then that unscrupulous exploiters of chemical preservatives took a leaf out of the note-book of "patent medicine" fakers and put on the market, under fanciful names, preserving compounds composed largely of boric acid, but giving no indication of the presence of this chemical.

---

3. Edmunds and Hale: Hyg. Lab. Bull. No. 48.

Mrs. Price's Canning Compound is sold on the claim that it will "prevent canned fruits and vegetables from souring and spoiling" and that it "may be used in canning all kinds of fruits" and "in making catsup, sweet pickles or anything that is liable to ferment." The Kansas State Board of Health has published at different times the results of two independent analyses of this "compound." These indicated that the stuff varied in composition. In view of this fact and because inquiries have been received, another analysis was made of Mrs. Price's Canning Compound, in the Association laboratory. The report of the Association's chemists is as follows:

"Mrs. Price's Canning Compound, manufactured by the Price Compound Company, Minneapolis, Minn., as received in the Association laboratory, was contained in an envelope bearing the name of the preparation, the name and address of the manufacturer and directions for its use.

"The envelope contained about 30 gm. of a white powder, soluble in water, possessing a salty taste and having an odor of benzoic acid. Qualitative tests indicated the presence of borate, chlorid, benzoate and sodium. Further experiments and the quantitative estimations indicated that the constituents found existed as boric acid, sodium chlorid and benzoic acid (possibly in part as benzoate) corresponding to the following amounts:

Boric acid, 94.74 per cent.
Sodium chlorid, 4.71 per cent.
Benzoic acid (calculated from total benzoate), 0.40 per cent.

"While the first analysis (Bulletin Kansas State Board of Health, October, 1909, p. 267) showed that the preparation consisted entirely of commercial boric acid, the second examination (Bulletin Kansas State Board of Health, November, 1909, p. 282) showed that about 6 per cent. of the boric acid had been replaced by sodium chlorid. The present analysis shows that the composition has been again altered by the addition of a small amount of benzoic acid. For all practical purposes, these changes are unessential. The variability is evidently the result of carelessness in the manufacture or it is made with the idea of misleading and confusing."

The housewife who uses this mixture does so, of course, not knowing that the chemical she is putting into her foods has been declared injurious as a food preservative by the federal government. Neither does she realize that she is paying for what is essentially boric acid, worth 15 cents a pound, at the rate of $1.60 a pound.

Correspondence

The Philadelphia Idea as to Medical Teaching

To the Editor:—On several occasions within the last few years statements have been made in medical journals, here and abroad, to the effect that the medical schools of this country are not equipped with satisfactory opportunities for clinical teaching. Last spring, the president of Cornell University, when delivering an address which should have been carefully prepared, made the extraordinary statement that no medical school in this country, with the exception of Johns Hopkins, had a hospital completely under its control, and therefore adequately used for teaching purposes.

In the London *Lancet*, Feb. 4, 1911, its American correspondent in describing a proposed amalgamation between the medical department of Columbia University and the Presbyterian Hospital refers to this plan as the "Johns Hopkins idea." It goes without saying that those of us who know much of medical teaching hold the Johns Hopkins Medical Department in the highest esteem, but it is only proper that the facts be correctly stated. The object of this communication is to point out the fact (not so generally known as it should be) that every medical school in Philadelphia has as a part of its equipment a hospital, which exists, not as an affiliated institution, but as part and parcel of its teaching plant. As long ago as 1824, when Jefferson Medical College was founded, it established an out-patient service in order to give its students the advantage of clinical material under its own control; and in 1841, the medical department of the University of Pennsylvania did likewise. In 1873, Jefferson Medical College inaugurated its plans for a complete hospital, and this institution was opened Sept. 17, 1877, containing 160 beds. At about the same time the Hospital of the University of Pennsylvania went into active service. Three years ago, the new Jefferson Medical College Hospital, costing $1,250,000, was completed, containing 300 beds, and from time to time the university hospital has been considerably enlarged. As soon as it was started in 1881 the Medico-Chirurgical College established an out-patient department, and a few years afterward erected a hospital. The Woman's Medical College of Pennsylvania also has a hospital known as the Hospital of the Woman's Medical College. The Hahnemann Medical College also has its own hospital, and the medical department of Temple University, the youngest of the Philadelphia schools, has under its direct control the Samaritan Hospital.

It is interesting to note in this connection that all of these hospitals are under the control of the same boards of trustees that govern the institutions in which the students matriculate for the purpose of studying medicine, and in the Jefferson Medical College, in the University Medical Department and in the Medico-Chirurgical College members of the faculty who teach in the practical branches are by virtue of their professorial chairs in actual control of and on duty in the wards. In other words, to be elected professor of medicine, therapeutics, or surgery in Jefferson Medical College means that a man is thereby elected physician or surgeon to the Jefferson Medical College Hospital. The relationship is therefore a matter of absolute control and not of friendly affiliation, and by this means only can satisfactory medical teaching in a medical school be accomplished. If, therefore, the principle of having an active hospital as a part of a thoroughly equipped medical school is to be given a specific name it should be called the "Jefferson Medical College idea" or the "Philadelphia idea" and not the "Johns Hopkins idea."

As a matter of fact, barring the Johns Hopkins Hospital; there is, I believe, no medical school in the United States so thoroughly equipped with hospital facilities under its own control as the Philadelphia medical teaching institutions, all of which have their hospitals, with exception of Temple College, side by side with the medical school buildings. All of these institutions have in addition the opportunity of teaching their students in large hospitals which are thrown open to all the schools, such as the Pennsylvania and Philadelphia Hospitals, for example. In other words, the Philadelphia schools have all the benefits of unattached hospitals possessed by institutions elsewhere in addition to the ownership and control of their own hospitals.

As a matter of historical fact, Jefferson Medical College was the first medical institution in America to establish clinical teaching, and all its sister institutions in Philadelphia, with which it dwells in the most cordial friendship, have followed its example.

H. A. HARE, M.D., Philadelphia.
Professor of Therapeutics, and Physician to the Jefferson Medical College Hospital.

Card System of Dairy Inspection

To the Editor:—I notice with much interest an editorial in THE JOURNAL, Jan. 14, 1911, p. 124, relative to the score-card system of dairy inspection, which you commend, but say that it needs "further elaboration." I shall be much interested in seeing your comments on the card and getting your ideas on the same. Possibly a few words relative to the history and development of the standard card now in use may be helpful to you and of interest. The first score-card which I ever saw allowed 500 points and handed out blocks of twenty-five to thirty-five for different items. It soon became evident that such a card, as you say, needed "further elaboration;" that if twenty-five points were allowed, for instance, for "Cleanliness of the Stable," there would be a chance for very wide differences in the score; so that from time to time we have revised the score-card until we have evolved the one which we recommend, and every revision has been along the line of this "further elaboration." The one which we are using now has the endorsement of the National Association of Official Dairy Instructors, but when we print more of them two items at least will receive, doubtless, further elaboration. The eight points allowed for "Cleanliness of Cows" will be subdivided into minor items, as will be the six points for "Condition of Stable," "Air at Milking Time," giving a part of the allowance for "Clean Bedding," a part for "Freedom from Dust," and a part for "Freedom from Odors." Our experience has shown us that the more the card is elaborated the better it is, and the present card is the result of years of experience and development along that line.

GEORGE M. WHITAKER,
In Charge, Market Milk Section, Dairy Division.
U. S. Dept. Agriculture, Bureau of Animal Industry.

[COMMENT:—Editorial reference to this subject is made in this issue.—ED.]

Peccavimus!

To the Editor:—I have been frequently amused by the quality of medical erudition displayed by the daily and weekly newspapers; especially by the "Clippings from Lay Exchanges" in THE JOURNAL. But are we not the goat of the Roman fable, standing on the roof of a house and ridiculing the wolf passing below, when our great JOURNAL, the English of which is so polished and the proofreading so nearly perfect, prints (Feb. 11, 1911, p. 443) Latin like this: "M. fiat pilulam"? Should the author of such Latin take up his long-neglected "Commentarii Cæsaris de Bello Gallico" and find such a distortion of case-endings he would certainly be puzzled if he made an effort to convert it into English.

CHARLES H. HIGGINS, Zanesville, O.

[COMMENT:—We wish here to acknowledge other letters on this subject and to admit that our correspondent's severity is not misplaced. The error cited is, of course, a shocking one. We desire, however, to exculpate completely Dr. Bolenius, who furnished the prescriptions. We can only plead guilty of an inexplicable blunder, and throw ourselves on the mercy of the court. Those of our readers who have had any experience with the treachery of types will perhaps be lenient. If Argus had had brains to match his hundred eyes, he would have been just the man we want on our staff. Evidently, however, we have the next best thing— a corps of readers whose collective erudition and interest in maintaining the standard of THE JOURNAL are so great that any oversight of ours is sure to be brought to our attention in the next mail.—ED.]

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

MARSDEN'S PASTE

To the Editor:—Who was the originator of Marsden's paste? Who is or was Marsden? Please give the percentage of epitheliomas cured by it.

I have had excellent success in one case of epithelioma of the bridge of the nose and toward the inner canthus of the left eye with this paste. But a man of 80 presented himself with an extended growth reaching within quarter of an inch of the margin of the lower eyelid, and I have put him off, hardly daring to do anything. Any suggestion will be thankfully received. . If Marsden's paste is a good treatment, why is it not emphasized more?

A. I. LOVELL, M.D., Graysville, Tenn.

ANSWER.—Alexander Marsden originated this paste. He was a London surgeon who had a large experience in cancer in the London Cancer Hospital. His paste was introduced in an article, "A New and Successful Mode of Treating Cancer," published in London in 1867. It has always been highly regarded and widely used by a few men, but, like all other caustic methods of treating epitheliomas, it has suffered from the prejudice against caustics. It is a valuable method of treatment in properly selected cases. Its use, with that of other caustics, is considered in detail in THE JOURNAL, Nov. 5, 1910, p. 1611, in the article by Dr. W. A. Pusey on "Treatment of Malignant Growths of the Skin from a Dermatologist's Standpoint."

No reliable statistics are possible as to the percentage of cures obtained with it. Success depends on its thorough application in properly selected cases—that is, in cases in which the growth can be entirely destroyed. Daniel Lewis says that 99 per cent. of epitheliomas of the skin are curable if taken in time.

SPENGLER'S IMMUNE BODIES—I K .

To the Editor:—1. What is the Carl Spengler immune blood or antitoxin? 2. Where can it be obtained? 3. What results have been obtained from its use in tuberculosis?

JOSEPH PESTAL, M.D., Pearce, Ariz.

ANSWER.—1. Carl Spengler's immune bodies—I K—are derived from the red blood-corpuscles of the blood of animals immunized against the tubercle bacillus. The material is said to be extracted in such a way that the immune bodies are removed in a state of comparative purity, free from albumin and blood-coloring matter. The theory of Spengler, on which the preparation is based, is that the red blood-corpuscles are the source of the immunizing substance produced by the organism in tuberculosis.

2. The preparation is made by Spengler, of Davos, Switzerland, and is put on the market by Kalle & Co., Biebrich a. Rh., Germany. It has been used to a considerable extent in Germany, but, as we understand, it cannot be imported into this country legally because the firm which manufactures it has not a license for the manufacture of serums, antitoxins, tuberculins, etc., which is required by the United States government before such products can be imported into this country. A list of licensed manufacturers appeared in *Public Health Reports*, Feb. 10, 1911.

3. Many favorable reports of the action of this preparation in tuberculosis have appeared in the literature, while other clinicians have found it of little or no value. Further experience will be necessary before a positive opinion can be expressed.

TREATMENT OF GEOGRAPHICAL TONGUE

To the Editor:—Can you give me a remedy for a disease which is commonly known as "geographical tongue?" This is mentioned in Stelw [illegible] e Skin," on pp. 1086-89, under the heading of [illegible] laques of the Tongue," and is given the follow [illegible] areata linguæ, pityriasis linguæ, wandering [illegible] patches of the tongue, Muller's superficial [illegible]

I have under treatment a chronic case which has existed for about ten years; the patient is over 65 years of age and has no syphilitic taint. I have tried a number of antiseptics and other remedies, but I find them of very little use and would be grateful if you can suggest some remedy.

J. F. NAGLE, M.D., New York City.

ANSWER.—There is no satisfactory treatment for geographical tongue. Its etiology is not known, so the treatment is entirely empirical. The use of bland antiseptic mouth washes, such as a solution of hydrogen peroxid, and painting with a bland varnish, such as tincture of myrrh, are recommended. A few paintings with tincture of iodin at intervals of at least three or four days may serve to remove it either by stimulating the surface or by acting as an antiseptic. The condition is rare in the old and a careful differential diagnosis, should be made from leukoplakia, in which stimulating remedies like tincture of iodin are not indicated.

USE OF MERCURY CYANID OR OXYCYANID AS AN ANTISEPTIC

To the Editor:—Can you give me any references to literature concerning cyanid or oxycyanid of mercury as an antiseptic?

C. S. OAKMAN, *Detroit*

ANSWER.—Cyanid and oxycyanid of mercury are described in New and Nonofficial Remedies, pages 126 and 127, and in the British Pharmaceutical Codex. These authorities state that these salts have an antiseptic and disinfectant power similar to mercuric chlorid. The bactericidal value of mercuric oxycyanid is given by Lehmann (*Oesterr. Ztg.*, 1903, 851; abstracted in the Proceedings of the American Pharmaceutical Association, 1904, lii, 795) as equal to that of mercuric chlorid. Doubt is thrown on the antiseptic value of mercuric oxycyanid by K. Holdermann, who cites the experiments of B. Köhler in a thesis published at Marburg in 1905 (*Arch. d. Pharm.*, 243, No. 9, 1905, 673; abstracted in the Proceedings of the American Pharmaceutical Association, 1906, liv, 828)

MEDICAL MISSIONARY SERVICE

To the Editor:—Whom may one address to apply for foreign missionary medical service? F. S. MARNELL, Nebraska City, Neb.

ANSWER.—The first and most natural procedure for a person who wishes to take up foreign medical missionary work is to communicate with the foreign board or society of the particular denomination in which he or she is already a member or regular attendant. There is, however, what might be called a clearing house for all denominations, and the secretary of this body recently sent an interesting letter to THE JOURNAL, which will be found in the issue of Dec. 3, 1910, page 1997. Mr. W. B. Smith, 125 East Twenty-Seventh Street, New York City, is candidate secretary of the Student Volunteer Movement for Foreign Missions.

REMOVAL OF ADHESIVE PLASTER

To the Editor:—Dr. Beardsley, in THE JOURNAL, January 28, suggests the use of oil of wintergreen in removing adhesive plaster. A cheaper and often more accessible article is ether.

To remove the plaster raise from one-eighth to one-fourth inch of one end of the adhesive strap before applying the ether, then, with a medicine dropper, apply ether to the skin a drop at a time, and the plaster will almost fall off by its own weight. It is necessary to be careful not to separate the cloth from the adhesive material in starting or else the ether will follow this plane, removing the cloth only. J. SCOTT BROWN, M.D., Burnett, Wis.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Feb. 18, 1911.

Millikin, John D., D.S., granted leave of absence for two months, to take effect on arrival at San Francisco.

Moncrief, William H., captain, assignment to duty at Fort Riley, Kan., revoked, and instead ordered to Fort Leavenworth, Kan.

Graham, George D., D.S., orders so amended as to relieve him from duty at Fort Shafter, H. T., to take effect on the arrival at Honolulu of the transport leaving San Francisco about July 5, and to direct him to proceed on that transport to Manila, P. I., and report for assignment to duty.

Coffin, Jacob M., captain, granted three months' leave of absence, to take effect on his relief from duty in the Philippines division; permission to return to the United States via Europe.

Wing, F. F., D.S., reports his arrival at Fort Des Moines, Iowa, for temporary duty.

Pinkston, O. W., captain, reports in field with 4th Cavalry, camp at Washington Park, El Paso, Texas.

Millikin, John D., D.S., relieved from duty in the Philippines division and will proceed from Manila, P. I., about August 15, 1911, to San Francisco for orders.

Page, Henry, major, granted four months' leave of absence, to take effect on his relief from duty in the Philippines division, with permission to go beyond the seas.

McLaughlin, William F., M.R.C., granted leave of absence for one month and four days.

Blair, Faris M., M.R.C., granted twenty-three days' leave of absence.

Underwood, Gordon B., M.R.C., granted twenty-three days' leave of absence.

Delacroix, A. C., M.R.C., reported for temporary duty at Fort Columbia, Wash.; left Boise Barracks, Idaho, February 8.

Bierbower, H. C., M.R.C., reports arrival at Columbus, N. Mex., with Troop C, 4th Cavalry.

Maloney, James E., M.R.C., ordered to proceed to Fort Lawton, Wash., for temporary duty.

Campbell, George F., M.R.C., relieved from treatment at the Army and Navy General Hospital, Hot Springs, Ark., and will return to station, Fort Wingate, N. Mex.

Scott, Harold O., D.S., orders for annulment of contract revoked Will proceed, at the expiration of his leave of absence, to the Army General Hospital, San Francisco, for duty. Dental Surgeon Scott will stand relieved from duty at that hospital and will proceed to the Philippine Islands for duty on transport sailing from San Francisco about April 5, 1911.

Moncrief, William H., captain, granted thirty days' leave of absence.

Carr, William B., lieut., ordered to proceed from Fort Monroe, Va., to Fort Sam Houston, Texas, for temporary duty.

Delacroix, relieved from duty at Boise Barracks, Idaho, and assigned to duty at Fort Columbia, Wash.

Roberts, William M., major, ordered to Fort Oglethorpe, Ga., for temporary duty.

Bourke, James, captain, directed to proceed to Fort Crockett, Texas, for duty about April 10, insted of March 10, 1911.

Woodall, William P., captain, honorably discharged from the service of the U. S.

Williamson, L. P., lieut., assigned to duty with Co. I, Signal Corps, for field service in Arizona.

Medical Corps, U. S. Navy

Changes during the week ended Feb. 18, 1911.

Farwell, W. G., P. A. surgeon, detached from the naval station, Guantanamo, Cuba, and ordered to the *South Carolina*.

Riddick, W. J., asst.-surgeon, detached from the *South Carolina* and ordered to the naval station, Guantanamo, Cuba.

Hibbett, C. T., medical director, detached from the navy yard, Norfolk, Va., and ordered to command the naval hospital, Norfolk, Va.

Du Bose, W. R., medical director, detached from command of the naval hospital, Norfolk, Va., and ordered to duty as member of the naval examining and naval medical examining boards, Washington, D. C.

U. S. Public Health and Marine-Hospital Service

Changes for the seven days ended Feb. 15, 1911.

Guiteras, G. M., surgeon, granted nine days' leave of absence from Feb. 1, 1911, on account of sickness.

Young, G. B., surgeon, detailed to represent the service at the annual conference on medical education and legislation of the American Medical Association, at Chicago, March 1-3, 1911.

McLaughlin, A. J., P. A. surgeon, directed to proceed to Erie, via Harrisburg, Pa., on special temporary duty.

Warren, B. S., P. A. surgeon, granted seven days' leave of absence from Jan. 4, 1911.

Manning, H. M., P. A. surgeon, directed to proceed to the New Orleans quarantine station, Quarantine, La., and report to the medical officer in command, for duty and assignment to quarters.

Pettyjohn, Joseph, P. A. surgeon, directed to proceed to Boston and report to the medical officer in command for duty and assignment to quarters.

Lyon, R. H., asst.-surgeon, directed to proceed to Ellis Island, N. Y., and report to the chief medical officer for duty.

Stiles, C. W., professor of zoology, detailed to attend a conference on the hook-worm disease to be held at Atlanta, Ga., Feb. 14-15, 1911.

Hunt, Reid, professor of pharmacology, detailed to attend the meeting of the Council on Pharmacy and Chemistry of the American Medical Association, at Chicago, Feb. 17, 1911.

Thompson, W. R. P., A. A. surgeon, directed to proceed to Salina Cruz, Mexico, on special temporary duty.

Walkley, W. S., A. A. surgeon, granted seven days' leave of absence from Feb. 10, 1911.

Wood, J. E., A. A. surgeon, granted fifteen days' leave of absence from Feb. 9, 1911.

Wright, F. T., A. A. surgeon, granted thirty days' leave of absence from Feb. 6, 1911.

Motter, M. G., technical assistant, detailed to represent the service at the meeting of the National Confederation of State Medical Examining and Licensing Boards, at Chicago, Feb. 28, 1911.

Wilbert, M. I., technical assistant, detailed to attend the meeting of the Council on Pharmacy and Chemistry of the American Medical Association, at Chicago, Feb. 17, 1911.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

Senator Owen Introduces New Health Bill

The Hon. Robert L. Owen has introduced the following bill as a substitute for the bill introduced last year providing for a National Department of Health:

Be it enacted by the Senate and House of Representatives of the United States of America, in Congress assembled, That there shall be at the seat of government an executive department to be known as the Department of Health, and a Secretary of Health, who shall be the head thereof, who shall be appointed by the President, by and with the advice and consent of the Senate, who shall receive a salary of $12,000 per annum, and whose term and tenure of office shall be like that of the heads of the other executive departments; and Section 158 of the Revised Statutes is hereby amended to include such department, and the provisions of Title 4 of the Revised Statutes, including all amendments thereto, are hereby made applicable to said department. The said secretary shall cause a seal of office to be made for the said department, of such device as the President shall approve, and judicial notice shall be taken of said seal.

SEC. 2. That there shall be in said department an assistant
to the secretary, [illegible] and designated as director-general,
who shall be a [illegible] physician and a skilled sanitarian,
to be appointe [illegible] by and with the advice
and consent [illegible] receive a salary of
$7,500 per ann [illegible] ure of office shall
be for six [illegible] uties as shall be
prescribed by [illegible] There shall
also be one chi [illegible] other
clerical assist [illegible]
by Congress. A
ments shall rec
incidental [illegible]
[illegible] bureau
the
C

transferred to the Department of Health by executive order, as is provided for by this act, and to all other business within the jurisdiction of the Department of Health, and shall certify the balance arising thereon to the Division of Bookkeeping and Warrants, and send forthwith a copy of each certificate to the Secretary of Health.

SEC. 3. That it shall be the province and duty of said department to foster and promote, by inquiries or otherwise, and develop all matters pertaining to the public health; to collect and diffuse information relating to or affecting the public health; to advise the several departments of the government, the executives of the several states and territories, and all the health authorities of the several states and territories and the District of Columbia and the dependencies on all matters pertaining to the public health, when in his opinion such advice may tend to the preservation and improvement of the health of the people, to secure the best sanitary condition of vessels, their cargoes, passengers, and crews, from foreign and domestic ports; to prevent the introduction of contagious and infectious diseases into the United States and their spread from any state or territory or the District of Columbia; on request of the executive of any state or territory or the District of Columbia to cooperate with and aid state, territorial, district, and municipal health authorities in the execution and enforcement of such needful rules and regulations as are deemed by him necessary to suppress or prevent the spread of contagious and infectious diseases; and, in general, the Department of Health shall be the medium through which the government shall adopt such measures or take such action as will most effectually protect and promote the health of the people of the United States and its dependencies.

SEC. 4. That the office of the surgeon-general of the Public Health and Marine-Hospital Service and the corps of officers and personnel of the Public Health and Marine-Hospital Service, now and heretofore under the jurisdiction of the department of the Treasury, be, and the same hereby are, transferred from the Department of the Treasury to the Department of Health, and the same hereafter shall remain under the jurisdiction and supervision of the last-named department; and that the chief of and the Bureau of Vital Statistics of the Census Office, and all that pertains to the same, be, and the same hereby are, transferred from the Department of Commerce and Labor to the Department of Health and henceforth shall remain under the jurisdiction and supervision of the latter; and the following-named bureaus of the Department of Agriculture: that part of the Bureau of Chemistry charged with the investigation of the adulteration of foods, drugs, and liquors and engaged in the enforcement of the Act of Congress approved June 30, 1906, the chief of the bureau and all that pertains thereto, and that part of the Bureau of Animal Industry charged with the inspection of live cattle and hogs and carcasses and products thereof which are subjects of interstate and foreign commerce, the chief of the bureau and all of said bureau which pertains thereto, be, and the same hereby are, transferred to the Department of Health, and the same hereafter shall remain under the jurisdiction and supervision of the last-named department.

SEC. 5. That all the duties, powers, authority, and jurisdiction, whether supervisory, appellate, or otherwise, now imposed on the Secretary of the Treasury by acts of Congress relating to the Public Health and Marine-Hospital Service, to the enforcement of quarantine, and for the suppression of epidemic diseases; and now imposed on the Secretary of Commerce and Labor by acts of Congress, relating to the Bureau of Vital Statistics of the Census Office; and now imposed on the Secretary of Agriculture by acts of Congress, relating to that part of the Bureau of Chemistry charged with the investigation of the adulteration of foods, drugs, and liquors and engaged in the enforcement of the aforesaid Act of June 30, 1906, and relating to that part of the Bureau of Animal Industry charged with the inspection of live cattle and hogs and carcasses and products thereof, shall be, and the same hereby are, transferred to and imposed and conferred on the Secretary of Health.

SEC. 6. That the Secretary of Health is hereby given power and authority to rearrange the work of the bureaus and offices confided to said department, and to consolidate the statistical bureaus and offices, and the Secretary of Health shall also have authority to call on other departments of the government for statistical information so obtained in such manner as to him may seem wise. That the official records and papers now on file in and pertaining exclusively to the business of any bureau, office, department, or branch of the public service in this act transferred to the Department of Health, together with the furniture now in use in such bureau, office, or department, or branch of the public service, shall be, and hereby are, transferred to the Department of Health.

SEC. 7. That the President be, and hereby is, authorized by order in writing, to transfer at any time the whole or part of any office, bureau, division, or other branch of the public service engaged in statistical or scientific work which relates to and is germane to the public health to the Department of Health, except those of the Department of War and the Navy, and in every such case the duties and authority performed by and conferred by law on such office, bureau, division, or other branch of the public service, or part thereof, which is transferred, and all the power and authority conferred by law, both supervisory and appellate, on the department from which such transfer is made, or the secretary thereof, in relation to said office, bureau, division, or other branch of the public service, or the part thereof so transferred, shall immediately, when such transfer is ordered by the President, be fully conferred on and vested in the Department of Health or the secretary thereof, as the case may be, as to the whole or part of such office, bureau, division, or any branch of the public service so transferred.

SEC. 8. That there shall be an advisory board for the Department of Health. Said board shall consist of three competent experts, to be detailed from the Army, Navy, and the Bureau of Animal Industry by the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Secretary of Agriculture, and one versed in law to be detailed from the Department of Justice by the Attorney-General, respectively (which experts, together with the chiefs of the bureaus of the Department of Health, shall be *ex officio* members of the board, and serve without additional compensation), and eight other members who shall be appointed by the Secretary of Health, who shall be competent experts, and not in the regular employment of the government. The said eight members shall each receive compensation of $20 per diem while serving in conference, as aforesaid, together with allowance for actual and necessary traveling expenses and hotel expenses while in conference. The term of service of the eight members of said board not in the regular employment of the government, first appointed, shall be so arranged that two of said members shall retire each year, and subsequent appointments shall be for six years. Appointments to fill vacancies occurring in a manner other than as above provided shall be made for the unexpired term of the member whose place has become vacant. The duties of said board shall be to consult with the secretary relative to investigati[illegible] in the department and the methods of [illegible], to formulate, for the secretary's approval, the rules and regulations to be observed in maritime and interstate quarantine, to formulate opinions on subjects referred to it by the secretary, and to participate in conferences held by the Secretary of Health with the health authorities of states and territories and the District of Columbia; and so much of the act approved July 1, 1902, which relates to an advisory board for the Hygienic Laboratory is hereby repealed.

SEC. 9. That the Secretary of Health shall call an annual conference of the health authorities of all the states and territories and the District of Columbia, said conference to be held in the city of Washington, and each of the said states, territories, and the District of Columbia shall be entitled to send one delegate from its health department. And each delegate from said state or territory or the District of Columbia so attending a conference called by the Secretary of Health shall be entitled to receive an allowance for actual and necessary traveling expenses and hotel expenses, not exceeding five days, exclusive of days necessarily spent in travel: *Provided*, That when, in the opinion of the Secretary of Health, the interests of the public health would be promoted by a conference of one or more health authorities of states and territories with himself, he may invite such states and territories as he may deem necessary to send one delegate from each of the health departments to participate in such conference: *And provided further*, That it shall be the duty of the Secretary of Health to call a conference on application of not less than five state or territorial boards of health, and each of said states and territories and the District of Columbia joining in such request shall be entitled to send one delegate.

SEC. 10. That the Secretary of Health, after conference with the advisory board, may cause investigations to be made into the nature, origin, and prevention of contagious and infectious diseases, epidemics, and other diseases, in the

MEDICAL MISSIONARY SERVICE

To the Editor:—Whom may one address to apply for foreign missionary medical service? F. S. Marnell, Nebraska City, Neb.

Answer.—The first and most natural procedure for a person who wishes to take up foreign medical missionary work is to communicate with the foreign board or society of the particular denomination in which he or she is already a member or regular attendant. There is, however, what might be called a clearing house for all denominations, and the secretary of this body recently sent an interesting letter to The Journal, which will be found in the issue of Dec. 3, 1910, page 1997. Mr. W. B. Smith, 125 East Twenty-Seventh Street, New York City, is candidate secretary of the Student Volunteer Movement for Foreign Missions.

REMOVAL OF ADHESIVE PLASTER

To the Editor:—Dr. Beardsley, in The Journal, January 28, suggests the use of oil of wintergreen in removing adhesive plaster. A cheaper and often more accessible article is ether.

To remove the plaster raise from one-eighth to one-fourth inch of one end of the adhesive strap before applying the ether, then, with a medicine dropper, apply ether to the skin a drop at a time, and the plaster will almost fall off by its own weight. It is necessary to be careful not to separate the cloth from the adhesive material in starting or else the ether will follow this plane, removing the cloth only. J. Scott Brown, M.D., Burnett, Wis.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Feb. 18, 1911.

Millikin, John D., D.S., granted leave of absence for two months, to take effect on arrival at San Francisco.

Moncrief, William H., captain, assignment to duty at Fort Riley, Kan., revoked, and instead ordered to Fort Leavenworth, Kan.

Graham, George D., D.S., orders so amended as to relieve him from duty at Fort Shafter, H. T., to take effect on the arrival at Honolulu of the transport leaving San Francisco about July 5, and to direct him to proceed on that transport to Manila, P. I., and report for assignment to duty.

Coffin, Jacob M., captain, granted three months' leave of absence, to take effect on his relief from duty in the Philippines division; permission to return to the United States via Europe.

Wing, F. F., D.S., reports his arrival at Fort Des Moines, Iowa, for temporary duty.

Pinkston, O. W., captain, reports in field with 4th Cavalry, camp at Washington Park, El Paso, Texas.

Millikin, John D., D.S., relieved from duty in the Philippines division and will proceed from Manila, P. I., about August 15, 1911, to San Francisco for orders.

Page, Henry, major, granted four months' leave of absence, to take effect on his relief from duty in the Philippines division, with permission to go beyond the seas.

McLaughlin, William F., M.R.C., granted leave of absence for one month and four days.

Blair, Faris M., M.R.C., granted twenty-three days' leave of absence.

Underwood, Gordon B., M.R.C., granted twenty-three days' leave of absence.

Delacroix, A. C., M.R.C., reported for temporary duty at Fort Columbia, Wash.; left Boise Barracks, Idaho, February 8.

Bierbower, H. C., M.R.C., reports arrival at Columbus, N. Mex., with Troop C, 4th Cavalry.

Maloney, James E., M.R.C., ordered to proceed to Fort Lawton, Wash., for temporary duty.

Campbell, George F., M.R.C., relieved from treatment at the Army and Navy General Hospital, Hot Springs, Ark., and will return to station, Fort Wingate, N. Mex.

Scott, Harold O., D.S., orders for annulment of contract revoked. Will proceed, at the expiration of his leave of absence, to the Army General Hospital, San Francisco, for duty. Dental Surgeon Scott will stand relieved from duty at that hospital and will proceed to the Philippine Islands for duty on transport sailing from San Francisco about April 5, 1911.

Moncrief, William H., captain, granted thirty days' leave of absence.

Carr, William B., lieut., ordered to proceed from Fort Monroe, Va., to Fort Sam Houston, Texas, for temporary duty.

Delacroix, relieved from duty at Boise Barracks, Idaho, and assigned to duty at Fort Columbia, Wash.

Roberts, William M., major, ordered to Fort Oglethorpe, Ga., for temporary duty.

Bourke, James, captain, directed to proceed to Fort Crockett, Texas, for duty about April 10, insted of March 10, 1911.

Woodall, William P., captain, honorably discharged from the service of the U. S.

Williamson, L. P., lieut., assigned to duty with Co. I, Signal Corps, for field service in Arizona.

Medical Corps, U. S. Navy

Changes during the week ended Feb. 18, 1911.

Farwell, W. G., P. A. surgeon, detached from the naval station, Guantanamo, Cuba, and ordered to the *South Carolina*.

Riddick, W. J., asst.-surgeon, detached from the *South Carolina* and ordered to the naval station, Guantanamo, Cuba.

Hibbett, C. T., medical director, detached from the navy yard, Norfolk, Va., and ordered to command the naval hospital, Norfolk, Va.

Du Bose, W. R., medical director, detached from command of the naval hospital, Norfolk, Va., and ordered to duty as member of the naval examining and naval medical examining boards, Washington, D. C.

U. S. Public Health and Marine-Hospital Service

Changes for the seven days ended Feb. 15, 1911.

Guiteras, G. M., surgeon, granted nine days' leave of absence from Feb. 1, 1911, on account of sickness.

Young, G. B., surgeon, detailed to represent the service at the annual conference on medical education and legislation of the American Medical Association, at Chicago, March 1-3, 1911.

McLaughlin, A. J., P. A. surgeon, directed to proceed to Erie, via Harrisburg, Pa., on special temporary duty.

Warren, B. S., P. A. surgeon, granted seven days' leave of absence from Jan. 4, 1911.

Manning, H. M., P. A. surgeon, directed to proceed to the New Orleans quarantine station, Quarantine, La., and report to the medical officer in command, for duty and assignment to quarters.

Pettyjohn, Joseph, P. A. surgeon, directed to proceed to Boston and report to the medical officer in command for duty and assignment to quarters.

Lyon, R. H., asst.-surgeon, directed to proceed to Ellis Island, N. Y., and report to the chief medical officer for duty.

Stiles, C. W., professor of zoology, detailed to attend a conference on the hook-worm disease to be held at Atlanta, Ga., Feb. 14-15, 1911.

Hunt, Reid, professor of pharmacology, detailed to attend the meeting of the Council on Pharmacy and Chemistry of the American Medical Association, at Chicago, Feb. 17, 1911.

Thompson, W. R. P., A. A. surgeon, directed to proceed to Salina Cruz, Mexico, on special temporary duty.

Walkley, W. S., A. A. surgeon, granted seven days' leave of absence from Feb. 10, 1911.

Wood, J. E., A. A. surgeon, granted fifteen days' leave of absence from Feb. 9, 1911.

Wright, F. T., A. A. surgeon, granted thirty days' leave of absence from Feb. 6, 1911.

Motter, M. G., technical assistant, detailed to represent the service at the meeting of the National Confederation of State Medical Examining and Licensing Boards, at Chicago, Feb. 28, 1911.

Wilbert, M. I., technical assistant, detailed to attend the meeting of the Council on Pharmacy and Chemistry of the American Medical Association, at Chicago, Feb. 17, 1911.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

Senator Owen Introduces New Health Bill

The Hon. Robert L. Owen has introduced the following bill as a substitute for the bill introduced last year providing for a National Department of Health:

Be it enacted by the Senate and House of Representatives of the United States of America, in Congress assembled, That there shall be at the seat of government an executive department to be known as the Department of Health, and a Secretary of Health, who shall be the head thereof, who shall be appointed by the President, by and with the advice and consent of the Senate, who shall receive a salary of $12,000 per annum, and whose term and tenure of office shall be like that of the heads of the other executive departments; and Section 158 of the Revised Statutes is hereby amended to include such department, and the provisions of Title 4 of the Revised Statutes, including all amendments thereto, are hereby made applicable to said department. The said secretary shall cause a seal of office to be made for the said department, of such device as the President shall approve, and judicial notice shall be taken of said seal.

Sec. 2. That there shall be in said department an assistant to the secretary, known and designated as director-general, who shall be a competent physician and a skilled sanitarian, to be appointed by the President, by and with the advice and consent of the Senate, who shall receive a salary of $7,500 per annum, and whose term and tenure of office shall be for six years. He shall perform such duties as shall be prescribed by the secretary or required by law. There shall also be one chief clerk, and a disbursing clerk and such other clerical assistants as may from time to time be authorized by Congress. And the auditor for the state and other departments shall receive and examine all accounts of salaries, and incidental expenses of the office of the Secretary of Health and of all bureaus and offices under his direction, all accounts relating to the Public Health and Marine-Hospital Service, the Bureau of Chemistry, the Bureau of Vital Statistics, the Bureau of Meat Inspection, or other bureaus which may be transferred to the Department of Health by executive order, as is provided for by this act, and to all other business within the jurisdiction of the Department of Health, and shall certify the balance arising thereon to the Division of Bookkeeping and Warrants, and send forthwith a copy of each certificate to the Secretary of Health.

SEC. 3. That it shall be the province and duty of said department to foster and promote, by inquiries or otherwise, and develop all matters pertaining to the public health; to collect and diffuse information relating to or affecting the public health; to advise the several departments of the government, the executives of the several states and territories, and all the health authorities of the several states and territories and the District of Columbia and the dependencies on all matters pertaining to the public health, when in his opinion such advice may tend to the preservation and improvement of the health of the people, to secure the best sanitary condition of vessels, their cargoes, passengers, and crews, from foreign and domestic ports; to prevent the introduction of contagious and infectious diseases into the United States and their spread from any state or territory or the District of Columbia; on request of the executive of any state or territory or the District of Columbia to cooperate with and aid state, territorial, district, and municipal health authorities in the execution and enforcement of such needful rules and regulations as are deemed by him necessary to suppress or prevent the spread of contagious and infectious diseases; and, in general, the Department of Health shall be the medium through which the government shall adopt such measures or take such action as will most effectually protect and promote the health of the people of the United States and its dependencies.

SEC. 4. That the office of the surgeon-general of the Public Health and Marine-Hospital Service and the corps of officers and personnel of the Public Health and Marine-Hospital Service, now and heretofore under the jurisdiction of the department of the Treasury, be, and the same hereby are, transferred from the Department of the Treasury to the Department of Health, and the same hereafter shall remain under the jurisdiction and supervision of the last-named department; and that the chief of and the Bureau of Vital Statistics of the Census Office, and all that pertains to the same, be, and the same hereby are, transferred from the Department of Commerce and Labor to the Department of Health and henceforth shall remain under the jurisdiction and supervision of the latter; and the following-named bureaus of the Department of Agriculture: that part of the Bureau of Chemistry charged with the investigation of the adulteration of foods, drugs, and liquors and engaged in the enforcement of the Act of Congress approved June 30, 1906, the chief of the bureau and all that pertains thereto, and that part of the Bureau of Animal Industry charged with the inspection of live cattle and hogs and carcasses and products thereof which are subjects of interstate and foreign commerce, the chief of the bureau and all of said bureau which pertains thereto, be, and the same hereby are, transferred to the Department of Health, and the same hereafter shall remain under the jurisdiction and supervision of the last-named department.

SEC. 5. That all the duties, powers, authority, and jurisdiction, whether supervisory, appellate, or otherwise, now imposed on the Secretary of the Treasury by acts of Congress relating to the Public Health and Marine-Hospital Service, to the enforcement of quarantine, and for the suppression of epidemic diseases; and now imposed on the Secretary of Commerce and Labor by acts of Congress, relating to the Bureau of Vital Statistics of the Census Office; and now imposed on the Secretary of Agriculture by acts of Congress, relating to that part of the Bureau of Chemistry charged with the investigation of the adulteration of foods, drugs, and liquors and engaged in the enforcement of the aforesaid Act of June 30, 1906, and relating to that part of the Bureau of Animal Industry charged with the inspection of live cattle and hogs and carcasses and products thereof, shall be, and the same hereby are, transferred to and imposed and conferred on the Secretary of Health.

SEC. 6. That the Secretary of Health is hereby given power and authority to rearrange the work of the bureaus and offices confided to said department, and to consolidate the statistical bureaus and offices, and the Secretary of Health shall also have authority to call on other departments of the government for statistical information so obtained in such manner as to him may seem wise. That the official records and papers now on file in and pertaining exclusively to the business of any bureau, office, department, or branch of the public service in this act transferred to the Department of Health, together with the furniture now in use in such bureau, office, or department, or branch of the public service, shall be, and hereby are, transferred to the Department of Health.

SEC. 7. That the President be, and hereby is, authorized by order in writing, to transfer at any time the whole or part of any office, bureau, division, or other branch of the public service engaged in statistical or scientific work which relates to and is germane to the public health to the Department of Health, except those of the Department of War and the Navy, and in every such case the duties and authority performed by and conferred by law on such office, bureau, division, or other branch of the public service, or part thereof, which is transferred, and all the power and authority conferred by law, both supervisory and appellate, on the department from which such transfer is made, or the secretary thereof, in relation to said office, bureau, division, or other branch of the public service, or the part thereof so transferred, shall immediately, when such transfer is ordered by the President, be fully conferred on and vested in the Department of Health or the secretary thereof, as the case may be, as to the whole or part of such office, bureau, division, or any branch of the public service so transferred.

SEC. 8. That there shall be an advisory board for the Department of Health. Said board shall consist of three competent experts, to be detailed from the Army, Navy, and the Bureau of Animal Industry by the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Secretary of Agriculture, and one versed in law to be detailed from the Department of Justice by the Attorney-General, respectively (which experts, together with the chiefs of the bureaus of the Department of Health, shall be *ex officio* members of the board, and serve without additional compensation), and eight other members who shall be appointed by the Secretary of Health, who shall be competent experts, and not in the regular employment of the government. The said eight members shall each receive compensation of $20 per diem while serving in conference, as aforesaid, together with allowance for actual and necessary traveling expenses and hotel expenses while in conference. The term of service of the eight members of said board not in the regular employment of the government, first appointed, shall be so arranged that two of said members shall retire each year, and subsequent appointments shall be for six years. Appointments to fill vacancies occurring in a manner other than as above provided shall be made for the unexpired term of the member whose place has become vacant. The duties of said board shall be to consult with the secretary relative to investigations to be inaugurated in the department and the methods of conducting the same, to formulate, for the secretary's approval, the rules and regulations to be observed in maritime and interstate quarantine, to formulate opinions on subjects referred to it by the secretary, and to participate in conferences held by the Secretary of Health with the health authorities of states and territories and the District of Columbia; and so much of the act approved July 1, 1902, which relates to an advisory board for the Hygienic Laboratory is hereby repealed.

SEC. 9. That the Secretary of Health shall call an annual conference of the health authorities of all the states and territories and the District of Columbia, said conference to be held in the city of Washington, and each of the said states, territories, and the District of Columbia shall be entitled to send one delegate from its health department. And each delegate from said state or territory or the District of Columbia so attending a conference called by the Secretary of Health shall be entitled to receive an allowance for actual and necessary traveling expenses and hotel expenses, not exceeding five days, exclusive of days necessarily spent in travel: *Provided*, That when, in the opinion of the Secretary of Health, the interests of the public health would be promoted by a conference of one or more health authorities of states and territories with himself, he may invite such states and territories as he may deem necessary to send one delegate from each of the health departments to participate in such conference: *And provided further*, That it shall b
the duty of the Secretary of Health to call a conference
application of not less than five state or territorial boards
health, and each of said states and territories and the
trict of Columbia joining in such request shall be en Rather
send one delegate.

SEC. 10. That the Secretary of Health, afte physician
with the advisory board, may cause investi nform to the
made into the nature, origin, and preventi oting discovery
and infectious disease, epidemics, and oth in general prac-

Medical Education and State Boards of Registration

COMING EXAMINATIONS

CONNECTICUT: Regular, City Hall, New Haven, March 14-15. Sec., Dr. Charles A. Tuttle; Homeopathic, Grace Hospital, New Haven, March 14. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, March 14. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

ILLINOIS: Coliseum Annex, Chicago, March 2-4. Sec., Dr. James A. Egan, Springfield.

MAINE: Portland, March 14-15. Sec., Dr. F. W. Searle, 806 Congress St., Portland.

MASSACHUSETTS: State House, Boston, March 14-16. Sec., Dr. Edwin B Harvey, Room 159, State House.

WYOMING: Laramie, March 7-9. Sec., Dr. J. B. Tyrrell.

Preliminary Educational Requirement in Indiana

The State Board of Medical Registration and Examination has decided on the outline of minimum preparatory work required which will become effective June 30, 1912. It is as follows:

1. Graduation from a regularly commissioned high school of Indiana, or from an equivalent school, such graduation to be evidenced by a certificate or diploma properly *signed*, or in lieu of such graduation formal documentary evidence satisfactory to the board of a full equivalent of such high school course.

2. In addition to the above, the applicant must submit formal documentary evidence that he has pursued successfully in a recognized college or university in resident courses extending over not less than eighteen calendar months, sufficient work, including the courses outlined below, to entitle him unconditionally to not less than one-half of the total credits required by said institution for the bachelor's degree in the courses of liberal arts or science.

Specific subjects required: For applicants matriculating under these requirements subsequent to June 30, 1912, the following subjects are specifically required to be included in the preparatory work: One year each of chemistry and biology, one of which shall be college work. Two years of college English. The remaining college work is unspecified, save that it must be taken in subjects commonly recognized as belonging in the course of liberal arts or sciences. College courses, professional or semiprofessional in their nature, will not be accepted as meeting in any part the above preliminary requirements of two years of college work.

This board will not offer or accept any examination in lieu of, or as a test of any substitute for the above required college work in liberal arts or sciences. In lieu of such college work there may be offered an equivalent amount of work in a normal or other school whose credits are transferable and acceptable to such recognized college or university as contemplated above. The board may require as evidence of this equivalency a certificate from a college or university acceptable to the board, stating the work is so acceptable by said institution.

Book Notices

PRINCIPLES OF THERAPEUTICS. By A. Manquat, National Correspondent to the Académie de Medicine. Translated by M. Simbad Gabriel, M.D. Cloth. Price, $3 net. Pp. 208. New York: D. Appleton & Co., 1910.

Basing his studies on the scientific advances of the last half century and on clinical experience and exact observations, the author attempts to lay down principles for the guidance of the young physician. He divides remedies into four classes: etiologic or nosocratic, organic and functional, symptomatic, and reparative.

In dealing with the action of medicines a most important distinction is made between toxic and utilizable actions, both of which are included by pharmacologists under the term "physiologic." The author defines toxic action as follows: "The action on the organism of any substance which, in a relatively small dose, is capable of producing reactional, material or functional disorders, remarkable by their intensity, duration or gravity, whether these disorders be immediately appreciable or secondary and more or less slow in development." He says, "It is now obvious how far we are from an equation between toxicity and death."

For actions which do not exceed the limits of normal reactions, he proposes the term "utilizable action," and expresses the belief that this distinction has practical importance of the highest order because experimenters recognizing it will no longer exhaustively investigate the toxic action of a substance; on the contrary, the utilizable actions will interest them. While therapeutics may occasionally avail itself of toxic actions, as in the use of atropin as a mydriatic, the object should be to avoid them as a rule.

Another point to be emphasized is that the physician must always consider the possibility that the toxic action of the drug may cooperate with the action of the poison of the disease and so increase the undesirable effect on the weakened organ. Thus attention is called to the possibility of doing harm by the addition of medicinal to morbid toxicity.

Posology next demands attention and the important principle developed here is the determination of doses according to the action desired and their modification in accordance with the susceptibility of the organism. Protest is made against the use of the largest dose tolerated, to which is opposed the principle of giving the smallest effective dose.

The variations of practice imposed by various external conditions and by the nature of the disease producing the symptoms are discussed in a chapter on medicinal opportunity. There is excellent advice in the chapter entitled "Primum non Nocere," in which is discussed how one may do harm and how one may avoid doing harm. The author conservatively advises not to seek the better when good is at hand. "Where traditional medicine has shown the harmlessness and regularity of action of certain successful practices, it is inopportune to try to do better by some novel doubtful method."

Manquat's opinion of formularies is thus expressed: "It is, therefore, not too much to say that one may kill by conforming to a very good formulary." The formulary can only give the dose appropriate for the ordinary case. While in ordinary cases of pneumonia, digitalis is well borne and does good in relatively large doses, there are other cases, indicated by acceleration of the pulse and embryocardia, in which an ordinary dose may do harm by adding a medicinal poison to the poison of the disease. "How," Manquat asks, "could a formulary intended especially to furnish practical details on the administration of medicines discuss such views?" Again we quote, "What shall we think of tables of maximum doses? As I have myself been guilty of the elaboration of one, I may be severe with them. They are worse than useless, for they may warrant dangerous therapeutic procedures. Almost all posology, based as it is on the theories of physiologic therapeutics, should be revised and reduced."

As a conclusion of this chapter, the author lays down a scheme of questions which the physician should ask himself in difficult cases, in order that he may not neglect any important considerations and may avoid the chance of doing harm. While it would be impracticable to employ these questions in every case, it would be excellent practice for every student and young practitioner to use them until this method becomes habitual with him.

In a separate chapter, Manquat gives his idea of a scientific method in the study and practice of therapeutics. The necessity of exact diagnosis and prognosis as elements in every therapeutic problem is emphasized. The worthlessness of many of the reports of so-called clinical observation is pointed out. Few medicines when first offered to physicians have, according to the author, been subjected to a series of studies calculated to establish their therapeutic value. The author insists that when invited to try a product, practitioners should have scientific reasons for taking it seriously. "In order to end the invasion of worthless remedies and specialties, physicians should, as a matter of principle, refuse to prescribe a medicine until it has fulfilled the conditions of previous studies described above. The task of studying on a patient the effect of a medicinal substance is already difficult enough without undertaking it in the absence of good reasons, even when this substance is offered as a harmless one. Our mission is to take care of patients: it is by no means that of making a reputation or a fortune for manufacturers, no matter how commendable they may be. When they say 'Try it anyhow; it is harmless,' we must answer that we try only what to us appears to be useful."

Another quotation will indicate the author's view of much current clinical observation: "Numbers add no more to the presumption of utility of a medicine than ciphers added to one another constitute a figure. A simple observation well made is of more value than a thousand of these pseudo-observations."

Space forbids a complete analysis of this excellent work. Enough has been given to indicate its method and scope. The discussion is not confined to theory, but is carried into practical details. While the ideas and suggestions will, many of them, seem self-evident to the experienced physician, a reading of the book will stimulate him to a systematic review of the principles on which he bases his therapeutic practice, while to the beginner in medicine so clear an exposition cannot fail to be of great value. The translation appears to be exceptionally well done, no trace of French idiom being observable.

CIVICS AND HEALTH. By William H. Allen, Secretary, Bureau of Municipal Research. With an Introduction by William T. Sedgwick, Professor of Biology in the Massachusetts Institute of Technology. Cloth. Price, $1.25. Pp. 411, with illustrations. Boston: Ginn & Co., 1910.

The need of a book on modern applied sanitation which would be technically correct, and at the same time popularly interesting, has often been emphasized. Dr. Allen's book is a sincere effort to supply this need. It is divided into five parts. In the first, Dr. Allen discusses health as a civic obligation, stating that the best index to community health is the physical welfare of school children. The second part is devoted to the various physical evils from which school children suffer and the means of recognizing them. The third part is devoted to methods, including such problems as tuberculosis, clean milk, school inspection, etc. The fourth deals with municipal and school organization for securing hygienic conditions, while the last part of the book is devoted to a consideration of alcohol, tobacco, "patent medicines," sex hygiene and various methods of popular propaganda.

As was recently noted in our editorial columns, Dr. Allen's book has been adopted as a text-book for a reading course by a number of the county societies and county teachers' institutions in Missouri. The book contains a large amount of data, well arranged and forcibly presented. It is to be regretted that the influence of the work and of the author have been impaired by a tendency toward extravagant and unwarranted statements in some particulars. One illustration will suffice. "The man who discovers a surgical appliance is forced by the ethics of his profession either to commercialize it and lose his professional standing or to abide the convenience of his colleagues and their learned organizations in testing it. Rather than be branded a quack, charlatan or crank, the physician keeps silent as to convictions which do not conform to the text-book. Many a life-saving, health-promoting discovery which ought to be taken up and incorporated in general prac-

United States and its dependencies, and, if necessary, in foreign countries, and may appoint commissions of experts from the Department of Health or experts not in the regular employment of the government to make such investigation as may in his judgment seem wise.

Sec. 11. That the President is hereby authorized, when requested by the Secretary of Health, and when the same can be done without prejudice to the public service, to detail officers from the several departments of the government for duty under the direction of the Secretary of Health to carry out the provisions of this act, and such officers while so detailed shall receive no additional compensation except for actual and necessary expenses incurred in the performance of such duties.

Sec. 12. That the Secretary of Health shall annually, at the close of the fiscal year, make a report in writing to Congress, giving an account of all money received and disbursed by him and his department in fostering and promoting the public health, and in matters relating thereto. He shall make special reports as he may be required to do by the President, or either house of Congress, or which he himself may deem necessary and urgent.

Sec. 13. That, except as expressly provided for by this act, nothing herein contained shall be construed as limiting or abrogating any function, right, or duty now imposed by law on any existing bureau or part of bureau; but such bureaus and parts of bureaus as are by this act transferred to the Department of Health shall continue, under direction of the Secretary of Health, to have such functions, duties, and rights as they have at the time of such transfer, and such parts of bureaus as are not transferred, in those cases where a part only is transferred, shall continue to have such functions, duties, and rights as they would have had if this act had not been passed.

Sec. 14. That the sum of ——— dollars be, and is hereby, appropriated to carry the provisions of this act into effect.

Sec. 15. That all acts or parts of acts inconsistent with this act are hereby repealed.

Sec. 16. That this act shall take effect on and after July 1, 1911.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
Bowling Green, Kentucky

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Seventh Month—Fourth Weekly Meeting

Infections Occurring in Surgical Diseases and Conditions

ERYSIPELAS

Etiology: *Streptococcus erysipelatis*, relation to *Streptococcus pyogenes*. Season, age, sex, previous attacks, traumatism, local abrasions. Infection may be (1) local (ectogenous), (2) lymphogenous, or (3) hematogenous.

Pathology: Changes in the skin and subcutaneous tissues. Extension to deeper structures, meninges, etc. Changes in endocardium, viscera.

Symptoms: Incubation, duration, prodromata. Invasion; general symptoms, chill, fever, vomiting, pulse, urine, nervous symptoms. Relation of constitutional symptoms to local lesions. Local symptoms; erysipelas erythematosum. Erysipelas vesiculosum, bullosum, pustulosum, gangrenosum. Erysipelas migrans, neonatorum.

Treatment: Prophylactic. Antisepsis. Puerperal cases. Reinfection. Diet.*

Constitutional Treatment: Medicinal. Serum treatment. Symptomatic treatment.

Local Treatment: Phenol, mercuric chlorid, ichthyol. Subcutaneous injections. Strapping.

TETANUS

~ogy: Bacillus of tetanus, staining and cultural charac- ties. Tetanus toxins. Wounds favoring growth of bacillus. Fourth-of-July tetanus.

Changes du Incubation period. duration. prodromata. Gen-
Farwell, W. G toms. Condition of wound. "Idiopathic"
Guantanamo, Cub
Riddick, W. J., .
and ordered to the n.

Clinical Types: Acute and chronic, tetanus neonatorum, puerperal tetanus, head tetanus.

Treatment: Prophylaxis.
Local treatment.
Serum-Therapy: Method of using serum and antitoxins.
Phenol treatment.
Medicinal Treatment.

Monthly Meeting

The Value of Blood-Examination in the Surgical Infections.
The Clinical Diagnosis of Septicemia, of Pyemia.
Prophylaxis of the Surgical Infections.

Extra Weekly Meeting

There can be an extra weekly meeting for the exhibition of cases and for the report of case histories by any of the members.

---

* Osler's Modern Medicine, iii, 533.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Connecticut: Regular, City Hall, New Haven, March 14-15. Sec., Dr. Charles A. Tuttle; Homeopathic, Grace Hospital, New Haven, March 14. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, March 14. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

Illinois: Coliseum Annex, Chicago, March 2-4. Sec., Dr. James A. Egan, Springfield.

Maine: Portland, March 14-15. Sec., Dr. F. W. Searle, 806 Congress St., Portland.

Massachusetts: State House, Boston, March 14-16. Sec., Dr. Edwin B. Harvey, Room 159, State House.

Wyoming: Laramie, March 7-9. Sec., Dr. J. B. Tyrrell.

Preliminary Educational Requirement in Indiana

The State Board of Medical Registration and Examination has decided on the outline of minimum preparatory work required which will become effective June 30, 1912. It is as follows:

1. Graduation from a regularly commissioned high school of Indiana, or from an equivalent school, such graduation to be evidenced by a certificate or diploma properly signed, or in lieu of such graduation formal documentary evidence satisfactory to the board of a full equivalent of such high school course.

2. In addition to the above, the applicant must submit formal documentary evidence that he has pursued successfully in a recognized college or university in resident courses extending over not less than eighteen calendar months, sufficient work, including the courses outlined below, to entitle him unconditionally to not less than one-half of the total credits required by said institution for the bachelor's degree in the courses of liberal arts or science.

Specific subjects required: For applicants matriculating under these requirements subsequent to June 30, 1912, the following subjects are specifically required to be included in the preparatory work: One year each of chemistry and biology, one of which shall be college work. Two years of college English. The remaining college work is unspecified, save that it must be taken in subjects commonly recognized as belonging in the course of liberal arts or sciences. College courses, professional or semiprofessional in their nature, will not be accepted as meeting in any part the above preliminary requirements of two years of college work.

This board will not offer or accept any examination in lieu of, or as a test of any substitute for the above required college work in liberal arts or sciences. In lieu of such college work there may be offered an equivalent amount of work in a normal or other school whose credits are transferable and acceptable to such recognized college or university as contemplated above. The board may require as evidence of this equivalency a certificate from a college or university acceptable to the board, stating the work is so acceptable by said institution.

Book Notices

Principles of Therapeutics. By A. Manquat, National Correspondent to the Académie de Medicine. Translated by M. Simbad Gabriel, M.D. Cloth. Price, $3 net. Pp. 298. New York: D. Appleton & Co., 1910.

Basing his studies on the scientific advances of the last half century and on clinical experience and exact observations, the author attempts to lay down principles for the guidance of the young physician. He divides remedies into four classes: etiologic or nosocratic, organic and functional, symptomatic, and reparative.

In dealing with the action of medicines a most important distinction is made between toxic and utilizable actions, both of which are included by pharmacologists under the term "physiologic." The author defines toxic action as follows: "The action on the organism of any substance which, in a relatively small dose, is capable of producing reactional, material or functional disorders, remarkable by their intensity, duration or gravity, whether these disorders be immediately appreciable or secondary and more or less slow in development." He says, "It is now obvious how far we are from an equation between toxicity and death."

For actions which do not exceed the limits of normal reactions, he proposes the term "utilizable action," and expresses the belief that this distinction has practical importance of the highest order because experimenters recognizing it will no longer exhaustively investigate the toxic action of a substance; on the contrary, the utilizable actions will interest them. While therapeutics may occasionally avail itself of toxic actions, as in the use of atropin as a mydriatic, the object should be to avoid them as a rule.

Another point to be emphasized is that the physician must always consider the possibility that the toxic action of the drug may cooperate with the action of the poison of the disease and so increase the undesirable effect on the weakened organ. Thus attention is called to the possibility of doing harm by the addition of medicinal to morbid toxicity.

Posology next demands attention and the important principle developed here is the determination of doses according to the action desired and their modification in accordance with the susceptibility of the organism. Protest is made against the use of the largest dose tolerated, to which is opposed the principle of giving the smallest effective dose.

The variations of practice imposed by various external conditions and by the nature of the disease producing the symptoms are discussed in a chapter on medicinal opportunity. There is excellent advice in the chapter entitled "Primum non Nocere," in which is discussed how one may do harm and how one may avoid doing harm. The author conservatively advises not to seek the better when good is at hand. "Where traditional medicine has shown the harmlessness and regularity of action of certain successful practices, it is inopportune to try to do better by some novel doubtful method."

Manquat's opinion of formularies is thus expressed: "It is, therefore, not too much to say that one may kill by conforming to a very good formulary." The formulary can only give the dose appropriate for the ordinary case. While in ordinary cases of pneumonia, digitalis is well borne and does good in relatively large doses, there are other cases, indicated by acceleration of the pulse and embryocardia, in which an ordinary dose may do harm by adding a medicinal poison to the poison of the disease. "How," Manquat asks, "could a formulary intended especially to furnish practical details on the administration of medicines discuss such views?" Again we quote, "What shall we think of tables of maximum doses? As I have myself been guilty of the elaboration of one, I may be severe with them. They are worse than useless, for they may warrant dangerous therapeutic procedures. Almost all posology, based as it is on the theories of physiologic therapeutics, should be revised and reduced."

As a conclusion of this chapter, the author lays down a scheme of questions which the physician should ask himself in difficult cases, in order that he may not neglect any important considerations and may avoid the chance of doing harm. While it would be impracticable to employ these questions in every case, it would be excellent practice for every student and young practitioner to use them until this method becomes habitual with him.

In a separate chapter, Manquat gives his idea of a scientific method in the study and practice of therapeutics. The necessity of exact diagnosis and prognosis as elements in every therapeutic problem is emphasized. The worthlessness of many of the reports of so-called clinical observation is pointed out. Few medicines when first offered to physicians have, according to the author, been subjected to a series of studies calculated to establish their therapeutic value. The author insists that when invited to try a product, practitioners should have scientific reasons for taking it seriously. "In order to end the invasion of worthless remedies and specialties, physicians should, as a matter of principle, refuse to prescribe a medicine until it has fulfilled the conditions of previous studies described above. The task of studying on a patient the effect of a medicinal substance is already difficult enough without undertaking it in the absence of good reasons, even when this substance is offered as a harmless one. Our mission is to take care of patients; it is by no means that of making a reputation or a fortune for manufacturers, no matter how commendable they may be. When they say 'Try it anyhow; it is harmless,' we must answer that we try only what to us appears to be useful."

Another quotation will indicate the author's view of much current clinical observation: "Numbers add no more to the presumption of utility of a medicine than ciphers added to one another constitute a figure. A simple observation well made is of more value than a thousand of these pseudo-observations."

Space forbids a complete analysis of this excellent work. Enough has been given to indicate its method and scope. The discussion is not confined to theory, but is carried into practical details. While the ideas and suggestions will, many of them, seem self-evident to the experienced physician, a reading of the book will stimulate him to a systematic review of the principles on which he bases his therapeutic practice, while to the beginner in medicine so clear an exposition cannot fail to be of great value. The translation appears to be exceptionally well done, no trace of French idiom being observable.

Civics and Health. By William H. Allen, Secretary, Bureau of Municipal Research. With an Introduction by William T. Sedgwick, Professor of Biology in the Massachusetts Institute of Technology. Cloth. Price, $1.25. Pp. 411, with illustrations. Boston: Ginn & Co., 1910.

The need of a book on modern applied sanitation which would be technically correct, and at the same time popularly interesting, has often been emphasized. Dr. Allen's book is a sincere effort to supply this need. It is divided into five parts. In the first, Dr. Allen discusses health as a civic obligation, stating that the best index to community health is the physical welfare of school children. The second part is devoted to the various physical evils from which school children suffer and the means of recognizing them. The third part is devoted to methods, including such problems as tuberculosis, clean milk, school inspection, etc. The fourth deals with municipal and school organization for securing hygienic conditions, while the last part of the book is devoted to a consideration of alcohol, tobacco, "patent medicines," sex hygiene and various methods of popular propaganda.

As was recently noted in our editorial columns, Dr. Allen's book has been adopted as a text-book for a reading course by a number of the county societies and county teachers' institutions in Missouri. The book contains a large amount of data, well arranged and forcibly presented. It is to be regretted that the influence of the work and of the author have been impaired by a tendency toward extravagant and unwarranted statements in some particulars. One illustration will suffice. "The man who discovers a surgical appliance is forced by the ethics of his profession either to commercialize it and lose his professional standing or to abide the convenience of his colleagues and their learned organizations in testing it. Rather than be branded a quack, charlatan or crank, the physician keeps silent as to convictions which do not conform to the text-book. Many a life-saving, health-promoting discovery which ought to be taken up and incorporated in general practice from one end of the country to the other and which should be made a part of the minimum standard of medical practice and medical agreement, must wait twenty-five or fifty years for recognition" (p. 272). Physicians who are conversant with medical literature know how constantly the verdict of the profession, as shown in current literature, entirely reverses the judgment of previously recognized "text-book" authorities. As to "life-saving, health-promoting" discoveries "waiting twenty-five or fifty years for recognition" this sweeping generalization has been repeatedly made, without the slightest grounds on which to base it. Can Dr. Allen point to a single "discovery," which, after a fair test proving it to be of any real value, failed to receive the recognition due it? Can he point to one, acceptance of which was delayed five years or even one year after its merits were established, to say nothing of twenty-five or fifty years? It is unfortunate that the influence of a much-needed and otherwise thoroughly valuable work should be impaired by such inaccurate and misleading statements.

PRIMER OF HYGIENE. By John W. Ritchie, Professor of Biology, College of William and Mary, Virginia, and Joseph S. Caldwell, Professor of Biology, George Peabody College for Teachers, Tennessee. Illustrated by Karl Hassmann and Hermann Heyer. Cloth. Price, 40 cents net. Pp. 184, with 113 illustrations. Yonkers-on-Hudson, N. Y.: World Book Co., 1910.

This is the first of a series of elementary books to be used as school text-books, called the New-World Science Series. The aim, which is the instruction of the young in the subjects of hygiene, sanitation and human physiology, is in line with the present wide interest in matters of health and preventive medicine. In the simplest language, enforced by illustrative examples that come within the range of knowledge and understanding of children for whom the book is intended, personal hygiene is taught in its various phases. The reasons for and the manner of taking care of the various organs and functions of the body are taught; the effects of improper habits of eating and drinking, the effects of alcohol and tobacco, tea and coffee, and the necessity for exercise are presented graphically. The germ origin of diseases is explained, and such diseases as typhoid fever, tuberculosis, malaria and small-pox are described, and the method of preventing these diseases and the importance of keeping up body resistance are entered into in a simple way. An understanding of these matters by the very young should be valuable in establishing correct hygienic habits that should prove of inestimable benefit in the prevention of disease throughout the life of the individual, and thereby have a notable influence in the betterment of public health conditions.

EMANUEL SWEDENBORG'S INVESTIGATIONS IN NATURAL SCIENCE AND THE BASIS FOR HIS STATEMENTS CONCERNING THE FUNCTIONS OF THE BRAIN. By Martin Ramstrom. (*Till Kungl. Vetenskaps-Societeten I Uppsala vid dess 200-Arsjubileum af Uppsala Universitet. Den 19 November, 1910.*) Paper. Pp. 59, with 4 illustrations. University of Uppsala, 1910

After a brief summary of Swedenborg's excursions into the fields of mathematics, astronomy, mechanics, chemistry, mineralogy and geology, the author presents more completely his later teachings on the structure and functions of the brain and a detailed analysis of the sources of these neurologic doctrines.

Although Swedenborg's neurology was permeated by the absurd ideas current in his time, and long afterward, regarding the nature of the "animal spirits" or "fluidum spiritosum" and the seat of the soul, nevertheless the reader cannot fail to be impressed by the great advance of his views over those of most of his contemporaries.

The most important of these are that the centers of the psychic functions are to be found in the cerebral cortex, that these functions are localized in definite cortical areas and that the cortical nerve cells ("cerebellula") are the functional units. All of these views are shown to be represented in more or less fragmentary forms scattered through various previous publications with which Swedenborg was doubtless familiar; but nowhere were they assembled in forms so similar to their modern phases as in Swedenborg's writings.

The explanation of his success in sifting the few kernels of reliable neurologic observation from the rubbish of current speculation and superstition is found in the fact that before publishing his works on the brain he devoted several years to anatomic, physiologic and clinical studies in various scientific centers of Europe and was thus prepared with a real, though limited, basis for a scientific treatment of the scanty neurologic data of his time.

This little work adds an interesting chapter to medical history, valuable for its accurate citations of the possible sources of Swedenborg's ideas from the works of Descartes, Willis, Malpighi, Vieussens and others.

BIENNIAL REPORT OF THE DAIRY AND FOOD COMMISSIONER OF WISCONSIN. For the Period Ending June 30, 1910. J. Q. Emery, Dairy and Food Commissioner, Madison, Wis. Cloth. Pp. 368, *with illustrations. 1910.*

A perusal of the report of the Wisconsin Dairy and Food Commission is convincing evidence of the fact that Wisconsin is one of the leading states in control of food, especially dairy products. The amount of work carried on during the term of two years is enormous, and the results seem to be excellent. There are records of 2,031 food analyses, and in addition 8,247 samples of milk have been analyzed. Systematic inspection of dairies has put the dairy industry on a relatively high level, and this industry is yielding an annual revenue of $79,000,000. Valuable statistics are given, and elaborate charts of the location of dairies, cheese factories, etc. An interesting comparison between early dairy conditions and the modern state of affairs are presented. The importance of a sanitary milk-supply is emphasized and regulations discussed for the production of clean milk.

The report states that food products with poisonous or deleterious chemical preservatives are almost completely driven from the Wisconsin market and that the labels state the true contents of the packages. Wisconsin has shown us that state control of food products, especially of dairy products, can be made successful, and has put before us a worthy example, which ought to serve as a guide for other states.

NURSES' HANDBOOK OF DRUGS AND SOLUTIONS. By Julia C. Stimson, *R. N., Vassar A.B.*, Superintendent of Nurses, Harlem Hospital of Bellevue and Allied Hospitals, New York City. Cloth. Price, $1 net. Pp. 82. Boston: Whitcomb & Barrows, 1910.

On the principle that it is beyond the nurse to prescribe, but that she should have a knowledge of the powerful and important drugs, the author has attempted to impart such knowledge. Drugs are first classified according to their more important physiologic action. In doing this the author has made the error of classifying chloral as an analgesic. Definitions and examples of the different preparations are given, as fluidextracts, tinctures, etc. Methods and indications for modification of doses, table of weights and measures and equivalents, method of preparing percentage solutions, formulas of solutions in common use, and very brief descriptions of the actions and uses of the more important drugs are given. Some exceptions might be taken to the list given under the head of practical classification of drugs; for instance, under acids, tannic and hydrocyanic acid are given. This would convey an erroneous idea of the action of these drugs. There is a list of Latin phrases and abbreviations, and the book closes with a chapter on serums, antitoxins and vaccines. The book contains useful information for the nurse, but it is not presented in a very attractive form.

THE DETERMINATION OF THE DETERIORATION OF MAIZE, WITH INCIDENTAL REFERENCE TO PELLAGRA. By O. F. Black and C. L. Alsberg, Chemical Biologists, Drug-Plant, Poisonous-Plant, Physiological, and Fermentation Investigations. Issued Dec. 16, 1910. Bull. 199, *Bureau of Plant* Industry, U. S. Department of Agriculture. Paper. Pp. 36. Washington: Government Printing Office, 1910.

This bulletin describes some work done in the Bureau of Plant Industry with reference to spoiled corn. This is preliminary to a further study to determine the possible connection between spoiled maize and pellagra. In the study of corn the Italians lay great stress on acidity. The bulletin describes methods of examining corn, by inspection, biologically and chemically, determining its acidity, which in sound corn should not be over 30 as measured by alkaline tests, its ash, fat, phenol and other reactions and the determination of its toxicity by animal experimentation; also a study of the micro-organisms which cause it to become moldy. The work is valuable as a foundation for the final determination of the rôle, if any, that spoiled maize plays in pellagra. No conclusion has been reached as yet. Many references to the literature are given.

THEORIE UND PRAXIS DER INNEREN MEDIZIN. Ein Lehrbuch für Studierende und Aerzte. Von Dr. Erich Kindborg in Bonn. Erster Band. Die Krankheiten der Zirkulations- und Respirationsorgane. Cloth. Price, 7 marks. Pp. 404, with 47 illustrations. Berlin: S. Karger, 1911.

The plan of this book is founded on the author's observation that students of practical medicine have frequently forgotten the pertinent facts learned in their preliminary studies of the fundamental sciences. Hence students are apt to pursue the subject of internal medicine with confused notions of the relations which chemistry, physiology and bacteriology bear to the subject at hand. Time is lost in referring to text-books, and the author has attempted to supply this lack by including, in his account of diseases, the essential facts of the fundamental sciences which find an application in the special case. The work is well done and may profitably be studied, not only by medical students but also by physicians who wish to review the subject.

MOTHERHOOD. A Manual on the Management of Pregnancy, the Preparation for and Conduct of Labor and the Principles and Methods of Infant-Feeding up to the Third Year of the Child's Life. Prepared especially for Mothers, Nurses and Students of Medicine. By Hudson D. Bishop, M.D., Visiting Obstetrician to the Maternity Hospital, Cleveland. Cloth. Price, $1.50 net. Pp. 244. Cleveland: Rose Publishing Co., 1910.

The author states in the preface that he has "endeavored to give everything, in a condensed form but in sufficient detail, that either the *mother* or nurse should know regarding the management of pregnancy, labor, and the lying-in, together with the care and feeding of the child." A book on this subject suitable for both mothers and nurses is an impossibility. It is unnecessary to alarm the expectant mother by informing her of all the symptoms and all the dangers of hemorrhage, abnormal presentations, puerperal sepsis, mastitis, phlegmasia alba dolens, etc.

Medicolegal

Unconstitutionality of Statute Taking Away Defense of Insanity, Etc.

The Supreme Court of Washington in the case of State vs. Strasburg (110 Pac. R. 1020) holds unconstitutional the statute of that state, enacted in 1909, which provides that "It shall be no defense to a person charged with the commission of a crime that at the time of its commission he was unable, by reason of his insanity, idiocy or imbecility, to comprehend the nature and quality of the act committed, or to understand that it was wrong; or that he was afflicted with a morbid propensity to commit prohibited acts; nor shall any testimony or other proof thereof be admitted in evidence."

The provisions of the state constitution especially considered were: "No person shall be deprived of life, liberty, or property without due process of law;" and, "The right of trial by jury shall remain inviolate." Consequently the court was confronted, as Justice Parker says, with the novel and grave question: Had the legislature the power under the constitution to enact a law taking away from a defendant accused of crime the opportunity to show in his defense the fact that at the time of the commission of the act charged as a crime against him he was insane, and, by reason, thereof, was unable to comprehend the nature and quality of the act committed? It is believed that this was the first instance of any such enactment. And an examination of a number of authorities is taken to show that the question of the insanity of the accused at the time of committing the act charged being one of fact when sought to be shown in his behalf, it is and always has been a question of fact for the jury to determine, as much so as any other question of fact bearing on the responsibility of the accused for the occurrence of the act relied on as constituting the offense charged.

According to the opinion prepared by Chief Justice Rudkin, if the act stopped with what is quoted above, there could be no question as to the legislative intent. For the first time in history, as far as the court was advised, the legislature of a civilized state has attempted to place the idiot, who hath no understanding from his nativity, the imbecile and the insane, who have lost their understanding through disease or mental decay, and the sane man, in the full possession of all his mental faculties, on an equal footing before the criminal law. But the legislature did not stop there.

Another section of the act provides that: "Whenever, in the judgment of the court trying the same, any person convicted of a crime shall have been at the time of its commission unable by reason of his insanity, idiocy or imbecility, to comprehend the nature and quality of his act, or to understand that it was wrong, or shall be at the time of his conviction or sentence insane, or an idiot, or imbecile, such court may in its discretion direct that such person be confined for treatment in one of the state hospitals for the insane, or in the insane ward of the state penitentiary, until such person shall have recovered his sanity. In determining whether any person convicted of a crime was at the time of the commission thereof unable by reason of his insanity, idiocy or imbecility to comprehend the nature and quality of his act, or to understand that it was wrong, or is at the time of his conviction or sentence insane or an idiot or imbecile, the court may take counsel with one or more experts in the diagnosis and treatment of insanity, idiocy and imbecility, and make such personal or other examination of the defendant as in his judgment may be necessary to aid him in the determination."

When these two sections are construed together, it is believed that the legislature did not intend to punish one for the commission of a crime, when by reason of his insanity, idiocy, or imbecility he was unable to comprehend the nature and quality of his act, or to understand that it was wrong, but rather that it intended to minimize the well-known evil resulting from the all-too-frequent interposition of the defense of insanity in homicide cases, where no other defense is available, by changing the time and mode of trial of the issue of insanity. But, assuming that the legislature simply intended to change the time and mode of trial of the issue of insanity, this latter-quoted section is lacking in every essential requirement of due process of law. While if the view must be accepted that the legislature intended to abrogate the defense of insanity in its entirety, and to place the sane and the insane, the idiot, and the imbecile on an equal footing before the criminal law, the opinion is still held that the act is unconstitutional and void.

The state sought to uphold the act on two grounds: first, on the ground that it is within the police power of the state to eliminate the question of intent in all criminal cases; and, second, on the ground that under modern theories the lawbreaker is taken into custody by the state for his own amelioration and reformation, and not as a punishment for crime—in other words, that the theory of legal punishment for crime is a relic of a barbarous age. But neither contention is accepted.

It will be conceded that the legislature has a broad discretion in defining and prescribing punishment for crime, but, broad and pervading as the police power is, it is not without constitutional limitations and restraints, and a valid penal law can scarcely be conceived of which would punish a man for the commission of an act which the utmost care and circumspection on his part would not enable him to avoid.

The argument that persons are no longer punished for their crimes is illusory and unsound. The man who is deprived of his liberty is punished, and you cannot change the fact by changing the name.

Exhibition of Body and Proof of Probability of Life

The Supreme Court of Pennsylvania says, in the personal injury case of Benson vs. Altoona & Logan Valley Electric Railway Co. (77 Atl. R. 492) that about five months after an accident in which the plaintiff was injured he was stricken with apoplexy which paralyzed his entire right side, and the real controversy at the trial was as to whether the paralytic condition was the result of the injuries received at the time of the accident or was due to a disease with which the defense claimed he was afflicted. The first assignments of error went to the refusal of the trial judge to compel the plaintiff to bare parts of his body for the examination of the jury. The plaintiff had submitted to a private physical examination by three physicians representing the defendant, and they were prepared to give their testimony as to the marks on his body. The Supreme Court holds that an exhibition of this kind to an unlearned jury is apt to do more harm than good, and the trial judge committed no error in refusing to order it in this case.

Nor does the court see any error in an instruction wherein the trial judge said to the jury: "There is no table of life probability adduced here in evidence, and I suppose counsel are afraid owing to the recent rulings of the Supreme Court to put in a life table, but it would be for you to look at this man and determine on the weight of the evidence from his appearance and from the evidence how long he would be likely to live, and, if his injury is permanent, then he ought to be compensated for the loss of earning power and for any pain and suffering that the weight of evidence shows he would endure in the future." The court says that, while life tables are admissible in evidence, the probability of life can be shown in other ways. In answering a request for an instruction, the trial judge told the jury that they should take into consideration the plaintiff's age, state of health, business habits, and manner of living. The suggestion that they might look at the plaintiff was expressly coupled with the instruction that their determination must rest on the weight of the evidence in the case.

CHICAGO PEDIATRIC SOCIETY

Regular Meeting, held Jan. 17, 1911

The President, Dr. John M. Dodson, in the Chair

Experimental Study of Allergy in Tuberculosis

Dr. H. F. Helmholtz: I investigated experimentally the relation of the point of inoculation and the size of the dose to the appearance and persistence of the cutaneous reaction. Forty-two guinea-pigs were inoculated in three series. In the first series, subcutaneous and intraperitoneal inoculations were compared; in the second series, intraperitoneal and intracardial inoculations were compared, and all three were compared in the third series. It was found that the injection of large doses of tubercle bacilli resulted fatally without producing an allergy demonstrable with the v. Pirquet test, in the majority of the intraperitoneal inoculations. Intracardially, a positive reaction resulted in a short time. Subcutaneously, all the pigs reacted. The same order also held for the small doses. The peritoneal inoculations gave rise to shorter periods of reactivity; the intracardial came next, and the subcutaneous gave the longest reaction. The interval between inoculation and first positive reaction varied from seven to one hundred days. The allergy varied from the first day to an indefinite period.

The microscopic examination of tuberculin reactions was undertaken in a series of strongly reacting pigs, both in normal and in tuberculous pigs, that were no longer reacting. The control and non-reacting animals showed practically no leukocytic infiltration. The sloughing extended slightly deeper in the latter than in the former. In the active reactions there was a thick slough in the area of scarification, separated from the normal tissue by a thick layer of purulent exudate, extending up to the surface on either side. The subcutaneous tissue, in the large reactions, had the typical appearance of an acute cellulitis, with the connective tissue elements widely separated by a fibrinous network, rich in polymorphonuclear cells.

In a series of six experiments, made to determine how soon the cutaneous reaction would appear after the peritoneal injection of tuberculous tissue, the animals were vaccinated every second day, beginning with the day after inoculation. On the sixteenth day after injections not a single animal had reacted positively; in fact, only three reactions occurred. Then, simultaneously, scarifications were made in the often vaccinated area, and in a hitherto unused portion of the skin. The animals all showed a strong positive reaction in the new area and practically none in the oft vaccinated area, with one exception, in which there was no reaction in either place. Only one animal showed a reaction in the old area. It is probable that this finding may be explained by assuming a using-up of the antibodies by the injected tuberculin, not sufficient antibodies remaining to combine with the tuberculin introduced through the scarified area to produce a reaction.

DISCUSSION

Dr. I. A. Abt: How do you explain the absence of the v. Pirquet reaction in cases of acute tuberculosis with fever?

Dr. H. F. Helmholtz: The disease process uses up the antibodies and none remains to unite with the tuberculin introduced by scarification. By using a large enough dose of tuberculin intracutaneously, a slight reaction usually results.

Dr. J. H. Hess: Schlossman claims that the injection of tuberculin increases immunity, while Hamburger holds that the disappearance of the cutaneous reaction to tuberculin reduces immunity.

Dr. H. F. Helmholtz: Observers generally disagree with Schlossman, asserting that by giving such large doses of tuberculin he merely uses up the available antibodies, and subsequent tests are negative. If the inoculations are interrupted for ten days or two weeks, the tuberculin test is again positive. I have caused the reaction to disappear by giving large doses of tuberculin.

Traumatic Diabetes in Children

Dr. S. Strauss: I have seen two cases of pancreatic diabetes following trauma. Both patients are alive and well. The first patient, aged 11, was hit by an automobile in July, 1907, and sustained a fracture of the right tibia. In February, 1908, he developed classical symptoms of diabetes. The v. Noorden gruel lowered the sugar output, but produced acidosis.

The second patient, aged 13, fell from a second story window, striking on his head. There was no evidence of injury. Three months afterward he had symptoms of diabetes. The v. Noorden diet invariably caused acetone to appear in the urine, and the ammonia coefficient was raised. The sugar output varied. The explanation probably is that the patient was suddenly switched from an ordinary diet to the v. Noorden diet without giving him a chance to regain his metabolism balance. A more gradual change of diet proved more satisfactory. At no time was there loss of body weight.

DISCUSSION

Dr. I. A. Abt: Diabetes in children usually results fatally, but these two cases were a revelation to me. Since then other similar cases have been reported. Of course, this is a different type of diabetes. Epstein showed that in 50 per cent. of these cases the trauma is to the head and in 50 per cent. elsewhere. We are in the habit of thinking that it is easy to produce diabetes if there is injury at the base of the fourth ventricle, yet these cases show that it may occur quite independently of any cerebral lesion. The matter of diet and acidosis was also interesting in these cases. When the patient was put suddenly on a different diet, there was either a rise in the ammonia coefficient curve or an increase in the sugar. When the patient was placed gradually on a different diet, these findings were not noted. It is difficult to feed these children the v. Noorden diet, because it is repulsive, and far from appetizing, but it is marvelous to see the good result when the patient is placed on this diet. The sugar disappears from the urine promptly. An observer in Budapest has reported a large series of cases of alimentary glycosuria in children who had been receiving malt foods. They were believed to be cases of pure diabetes, but when the carbohydrate was withheld the glycosuria disappeared. However, the two cases reported by Dr. Strauss were purely of traumatic origin, and not of the type of fatal diabetes mellitus so commonly seen in children.

DR. H. F. HELMHOLTZ: We know that the burning of carbohydrates in the body keeps the acidosis down, and when this does not take place, the acetone bodies are excreted in the urine. If carbohydrate is withheld entirely, the burning of fat is interfered with, and beta-oxybutyric acid accumulates in the body, and is excreted in the urine. In order to prevent this, therefore, there must be a burning of carbohydrates in the body. When the patients, therefore, were on the v. Noorden diet, they evidently burned all the carbohydrate given them, and when put on the other diet the sugar reappeared. These were not cases of diabetes where sugar is formed from proteids, so that the sugar found must have been introduced. The fact that the acidosis disappeared is absolute evidence that there were from 50 to 75 grams of carbohydrate being burned during that time. The acidosis is produced by an insufficiency of carbohydrates. When there are no carbohydrates in the body, the fats are burned and produce beta-oxybutyric acid. This acid cannot be oxidized any further, and is split into diacetic acid, and from that into acetone.

Study of Blood-Pressure in Normal Children

DR. MAY MICHAEL: In my studies I took into account not only the weight and height of the child, but also the circumference of the arm. I examined 128 children. The readings were taken as nearly as possible at the same time of day and under the same conditions. There was apparently an increase in the pressure with the increase in height and weight, but when the circumference of the arm was measured and the blood-pressure to the square millimeter estimated, the actual pressure was practically the same in a 5-year old child, 3 feet, 6 inches tall, weighing 40 pounds, as in a 15-year old child, 4 feet, 8 inches tall, weighing 90 pounds. According to Sallom, the area on which the pressure is exerted must be considered in estimating the blood-pressure, so that the actual blood-pressure must equal the height of the column of mercury, divided by the width of the cuff, multiplied by the circumference of the arm, which represents the area of the base. In the 128 children examined this formula did not vary more than 0.0014 mm., the mean pressure being 0.0070 mm., and the extreme 0.0084 mm. The formula is employed as follows: Multiply the arm circumference, 183 mm., by 90 mm., the width of the cuff. This equals 16,470 square millimeters, which is found to sustain 120 mm. of mercury. Therefore, one square millimeter will sustain 120/16,470, or 0.0072 mm., which represents the actual blood-pressure.

1 *Sporotrichosis in Man and in the Horse. R. L. Sutton, Kansas City, Mo.
2 The Special Relation of Modern Medicine to the Health of Women. A. C. Vietor, Boston.
3 Overgrowth of the Epiphysis of the Lower End of the Femur with an Obliteration of the Epiphyseal Line. J. W. Sever, Boston.
4 *Breast Abscess During Pregnancy. J. T. Williams, Boston

1. **Sporotrichosis in Man and in the Horse.**—Sutton reports one case seen by him. The disease was confined to the wrist and followed an injury resulting while the patient was repairing a manger at which fed a horse which had sporotrichosis of the neck. The usual line of treatment, potassium iodid in increasing dosage, gave excellent results in this instance. The lesion was somewhat resistant, probably because the infection was a mixed one (sporothrix and *Staphylococcus pyogenes aureus*), but it healed promptly under the daily application of gauze packs moistened with 1 per cent. liquor cresolis compositus.

4. **Breast Abscess During Pregnancy.**—Williams believes that 5.5 per cent. of all breast abscesses occur during pregnancy, and that organisms are present on the nipples in 100 per cent. and in the milk ducts in 86 per cent. of all pregnant women. When their growth is predisposed to by engorgement, or the resistance of the breast tissues is lowered by injury, or the organisms present are of unusual virulence, they attack the tissues and produce inflammation. The prophylaxis of breast abscess during pregnancy, according to Williams, consists in absolute cleanliness of the nipple, and the prompt treatment of mastitis by bandage, ice and saline catharsis.

18. **Influence of Pregnancy on Molluscum Fibrosum.**—In Hirst's patient, at the age of 18, four or five typical growths of molluscum fibrosum appeared on the anterior surface of the body, but did not increase in number. The woman married at twenty-five and became pregnant for the first time at twenty-six. During the first pregnancy the growths increased rapidly in number. After delivery, the numerical augmentation ceased, but the growths already developed remained. In each successive pregnancy, including the present, which is the seventh, there was an increase in the number of the growths, but no such increase in the intervals between the pregnancies. This case differs from Brickner's in the appearance of the disease to a very moderate degree before impregnation, in the absence of pigmentation, in the failure of the growths to disappear after delivery and in their greater size

and number. It differs from the cases described by dermatologists in the influence exerted on the progress of the disease by pregnancy.

19. **Myoma of the Uterus.**—The only point in which Deaver differs from those who believe in the higher percentage of malignant change, is in not advocating the removal of an accidentally discovered fibroid that is giving no symptoms. This, he says, is not a large class of cases and therefore, not a very important difference. Any tumor that begins to give trouble or to cause symptoms, even if only an irregular discharge, should be removed. The tendency toward malignant degeneration gives him one of the elements of his belief. The remainder are furnished by the greater frequency of troublesome non-malignant degeneration, the likelihood of hemorrhage and chronic anemia with cardiac and vascular disturbances, the frequency of pain and more or less dangerous pressure effects on the urinary tract, the intestines and surrounding organs, the proved failure of fibroids to cease from troubling with the menopause, and the certainty that in a large percentage of cases delay merely means operation later under less favorable conditions.

25. **Retroflexed Gravid Adherent Uterus.**—Werder reports briefly two cases coming under his observation of pregnancy in the retroflexed adherent uterus. He emphasizes two points in the treatment: (1) prompt operation as soon as the diagnosis under anesthesia has been confirmed; (2) separation of adhesions and reposition of uterus, but avoidance of all attempts at radical treatment or any other operative steps endangering the continuance of pregnancy. When operating before the end of the second month, the introduction of a pessary for a short period will prevent a return of the displacement without any danger to the fetus.

26. **Teaching Vagino-Abdominal Examination.**—Joint bimanual palpation is favored by Taussig. The essentials for accurate bimanual examination in his opinion are a knowledge of how the normal organs feel and where they lie in the pelvis, muscular relaxation of patient and physician, gentle manipulation and systematic exploration.

39. **Studies in Experimental Glycosuria.**—The distribution of glycogen over the liver, particularly during ether anesthesia and following the taking of food, and the average course of postmortem glycogenolysis (i. e., its time of onset and the velocity with which it proceeds), were two points investigated by Macleod and Pearce. They found that the percentage amount of glycogen in the different lobes of the liver varies by about 5 per cent. This variation, they think, is partly due to errors in the method of estimation (*Pflüger*) and partly because of an unequal amount of blood in different portions of the organ. These differences become greater (a) under ether anesthesia; (b) when the liver is left *in situ* in the dead animal, but are not materially affected by absorption of carbohydrate food from the intestine. After death in an etherized animal there is usually, but not always, an acceleration in the rate of glycogenolysis; this varies in different lobes. So far it has been impossible to determine the exact time of onset of post-mortem glycogenolysis, but it is certainly well established within twenty minutes after death. Once established, post-mortem glycogenolysis proceeds at a uniform speed for several hours after death, being dependent solely on the amount of glycogen remaining in the viscus (temperature, etc., being constant). Post-mortem glycogenolysis is much more active in intact than in cut up liver. In cut up liver, glycogenolysis is much more rapid when the liver is in contact with blood than when it is blood-free. The greater glycogenolysis in intact liver is not due to any influence which the nervous system might have during the few minutes after death in which it could still exert an influence. Stimulation of the great splanchnic has no constant influence on the course of post-mortem glycogenolysis.

40. **Metabolism of Dogs.**—From the experimental observations made by Underhill, it is apparent that as much as 39 per cent. of the small intestine of a dog may be short-circuited without causing significant detrimental changes in utilization of the various foodstuffs, and the animal may gain in weight. This statement is equally true when observations are made either at a period shortly after operation or at a period several months later. When as much as 66 per cent. of the small intestine has been functionally resected, the nutritive condition of the animal presents an entirely different aspect. Under these conditions, fat utilization is particularly decreased and the dog displays a decided tendency to furnish negative nitrogen balances. A small though steady loss of weight is slightly noticeable. Food utilization is in general apparently much better immediately after the operation than at a later period. In no animal observed did a material increase in fat intake cause significant change in the utilization of this or other foodstuff. When about three-quarters of the small intestine of the dog has been short-circuited, food utilization for the most part is seriously impaired, at least at a period several months after the operation. This is particularly true for fat utilization. Indican elimination through the urine is not materially altered under these conditions by replacement of meat in the diet with gelatin, an observation directly opposed to that obtained with the normal dog. The animal with a short-circuited intestine displays a greater ability to utilize carbohydrate than does the normal dog. Even though the carbohydrate intake may be much, in one case several times, greater than the normal animal requires, carbohydrate utilization is complete whether the test is made shortly after the operation or months later. This observation, Underhill believes, may prove of practical importance in the dietary treatment of the human subject who has undergone extensive intestinal resection.

51. **Medicinal Treatment of Diabetes Mellitus.**—For ordinary cases, Forchheimer prefers arsenic, given as liquor potassii arsenitis, in ascending doses, until mild toxic effects are produced; then the dosage should be gradually reduced. In order to get the best results from arsenic, mild toxic effects must be produced. This drug is especially indicated in severe cases, but it should always be combined with diet. It may also be given for general indications, and it is very valuable in neurotic, debilitated subjects. This drug does not increase sugar tolerance, and its effects gradually disappear when it is discontinued; unlike opium, never during its administration. Furthermore, in all the patients Forchheimer has treated, repeated courses have not lost their effect on the glycosuria and diminution of acetone bodies. Hexamethylenamin is especially valuable in such patients in whom diet regulation is impossible. At present, Forchheimer has employed it for five years, and given it in 5-grain doses, three or four times a day, an amount which has been, in one instance, continually taken for four months without any bad effects. With hexamethylenamin, glycosuria is improved and tolerance is increased. He does not recommend it for severe cases without proper diet.

In so far as belladonna is concerned, Forchheimer's results were the same whether he gave atropin methylbromid, atropin sulphate or belladonna itself. In a large number of cases glycosuria, and with it acetone bodies, have diminished or disappeared and carbohydrate tolerance was increased. Indeed, some of the patients were not dieting when taking this remedy, but when it was discontinued the sugar did not reappear for some time. In several severe cases it did no good. It seems perfectly adapted to milder cases, so that in one instance, without diet, there has been absence of sugar for over a year. In one case of diabetes in a child the disease ran its usual course, notwithstanding a strict adherence to Rudisch's directions as to diet and atropin methylbromid.

52. **Dietetic Treatment of Diabetes Mellitus.**—As a means of finding the type to which an individual case belongs, Foster emphasizes the importance of a diet representing approximately 125 grains of protein and 100 grams of carbohydrate, and which is equivalent to 3,200 calories. The patient is restricted absolutely to this diet, for two days, the urine being collected during the second twenty-four hours, and estimations made for the quantity of glucose and the presence and approximate amounts of diacetic and β-oxybutyric acids. The next step in the diet arrangement depends exclusively on this analysis. A number of illustrative cases are cited and recipes are given which for the most part were contributed by the families of patients.

53. **Résumé of Vaccine Therapy.**—While the medical literature abounds in articles on vaccine therapy, they are scattered through a large number of medical journals, covering several years. With the hope that by grouping together the cases from the literature, the reader may at a glance gain a better comprehension of the work being done and the results accomplished in this line, Stoner has written this paper. Its length prohibits the making of an abstract.

55. **Neural Atrophy of the Hand.**—In addition to the atrophic paralysis of the intrinsic muscles of the hand, of myelopathic and myopathic origin, Hunt believes that a neural type should also be recognized. Those of neural origin may be separated into two well-defined clinical types, both due to a compression lesion of a motor branch of a mixed nerve. These may be appropriately designated as follows: A hypothenar type, which term indicates the site of the compression at the base of the hypothenar eminence and its relationship to the ulnar nerve. A thenar type, which also indicates the site of the compression at the base of the thenar eminence, and the relationship to the median nerve.

56. **Association of Suppurative Disease.**—Coakley believes that the severer cases of acute rhinitis accompanied by acute infection of the nasal accessory sinuses are far more apt to be complicated by aural disease than the milder types of acute rhinitis. It is extremely rare for a patient with acute sinus disease, seen before acute otitis media has developed, to develop subsequently, during the course of the treatment, acute otitis media. Coakley is convinced that the early recognition of acute sinus disease, and appropriate treatment for its relief, will prevent many a patient from developing acute otitis media. The fact that acute otitis media usually occurs on the same side as the sinus disease inclines him to the belief that the pus from the various sinuses bathes the pharyngeal orifice of the Eustachian tube and is thence forced into and infects the tympanum. Patients with acute otitis media, associated with nasal accessory sinus disease, are more likely to develop such a degree of mastoiditis as to require a mastoid operation than patients with otitis not complicated by nasal accessory sinusitis. Coakley is inclined to believe, however, that some patients would repair the damage to the tympanum and mastoid if relieved of the added burden of the nasal disease. Patients suffering from chronic suppuration in the nasal sinuses are much less prone to acute otitis media than those having acute sinusitis. Coakley accounts for this in two ways: (a) The bacteria found in the pus in many cases of chronic sinusitis grow very poorly on any nutrient media; they seem to have lost much of their virulency. Should they be forced into the tympanum through the Eustachian tube, they may not infect the ear. (b) It is also probable that the antibodies in the chronic cases are a prevention against inciting a new infection. It is a well-known fact that after any operation, intranasal or external, in a case of chronic sinusitis, the virulency of the bacteria is greatly increased, owing to the wound secretions forming an excellent nutrient medium; hence the cellulitis or erysipelas which develops after some external operations in cases of chronic nasal accessory sinus disease.

58. **Myotonia Atrophica.**—Pemberton found that there is apparently no significant disturbance of the calcium output in muscular dystrophy; at least, in the presence of those phenomena which suggest Thomsen's disease. This can probably be inferred, though not surely, in regard to Thomsen's disease "*per se*." The creatinin output, however, under these circumstances may be considerably reduced and the creatinin co-efficient conspicuously low. Pemberton says that a consideration of the calcium, creatinin and general nitrogenous metabolism as recorded here, and in myasthenia gravis, may lead to information of value in classifying doubtful conditions of this nature and in localizing the perversions of function.

59. **Chronic Influenza.**—Jones' thesis is that influenza may be and frequently is a chronic intoxication. Chronic influenza in many respects certainly bears a close similarity to tuberculosis, and Jones has no doubt that many cases of chronic capillary bronchitis, pneumonia, bronchiectasis, etc., in which the disturbing factor was *Bacillus influenzæ*, have been diagnosticated tuberculosis. This has, in a way, been confirmed by his study of three cases, which clinically presented symptoms and physical signs of tuberculosis, but in which the tubercle bacillus could not be isolated. In man, therefore, the influenza bacillus must be regarded as capable of producing pathogenic processes without the aid of other organisms. The influenza bacillus must be regarded as the most important cause of a large number of cases of respiratory infection (acute and chronic) during the interepidemic periods; and as a contributing cause in many other cases when found mixed with the pneumococcus, *Micrococcus catarrhalis*, and other organisms. Patients may carry the organism in enormous numbers for years in their sputum, just as they have been shown to carry other common representatives of the flora of the respiratory tract. Jones believes that it is without question that organic and inorganic nerve disease results from acute influenza. Whether influenza is the original cause of psychoses acting as a chronic infection, or whether it is the contributing cause to a psychopathic basis, is a question. The history of influenzal epidemics has shown statistically that the mental and nerve force is lowered for a considerable time after the disappearance of the disease epidemically.

Bacillus influenzæ is responsible for a majority of cases of sinusitis, otitis, salpingitis, mastoiditis, and their sequels. The organism has been recovered in the discharge of more than 50 per cent. of patients suffering from suppurative otitis media, usually mixed with the pyogenic organisms.

60. **Mortality During the Early Weeks.**—Discussing the means of preventing *infant mortality* during the early weeks of life, Jacobi says:

> If you want to break up the *infant mortality* of the first weeks of life, see that your young doctors can be made competent and the indigent women supplied with a thoroughly informed midwife. As long as you cannot abolish dire poverty, give no rest to your legislatures, none to your health departments. No infant fit to live must be sacrificed through the absence of a competent and responsible midwife, who is taught enough of hygiene to prevent fatal mistakes and enough to know when it is time to send for a doctor. The women of the nation must be healthy, else the young will be feeble and sickly. But the vast majority of the confined women in the large cities have no time to recover. Tens of thousands get up after their confinement on the third or fourth day to do the washing and the rest. Instead of the two months, which is the shortest period in which the organs can become again normal, a few days are allowed, with scanty food and no attention, and a household to care for. A woman who has not sufficient time to recover will start and retain her pelvic inflammation and decrepitude. Her present child suffers and dwindles and dies; the future ones, if there be any, will be decrepit when born, and are counted, or will be counted, among the stillborn.

61. This article was also published in the *Montreal Medical Journal*, November, 1910, and *Surgery, Gynecology and Obstetrics*, January, 1911.

62. **The Diagnosis of Pleuritic Effusions in Infancy.**—Miller emphasizes the following points: Pleurisy with effusion is a common affection in infants under the age of 2 years. In the majority of cases it is purulent. Because of the disastrous, and even fatal, results of delay in, or mistakes of, diagnosis, it should be recognized early so that prompt—that is, surgical—treatment may be instituted. The diagnosis is often obscure, demanding, in the highest degree, carefulness, skill and experience. In arriving at a diagnosis, the antecedent affections should be fully appreciated. Of these, pneumonia is by far the most common. The general symptoms, as well as the physical signs, should be carefully weighed and considered. Of these, the latter are the more distinctive. The most reliable signs, in the order of their importance, are (1) exploratory puncture, (2) dulness with a sense of resistance, and (3) displacement of the apex. The other physical signs, so valuable in differentiating effusions in the adult, are uncertain, variable and confusing, and cannot be relied on in infants. The recognition of localized collections of fluid is especially puzzling, and demands great skill and watchfulness and a frequent resort to exploratory puncture or operation. The latter is safe, even when the lung is pierced, and particularly so when fluid is present. Notwithstanding the rare accidents that have followed this procedure, it should be employed to determine the character of the fluid, and, owing to the distressing results of unrecognized empyemas, it is imperatively demanded in all doubtful cases. The variability of the physical signs is a striking feature in infants and should always suggest an effusion.

63. **Proctoscopy and Sigmoidoscopy in Infancy.**—In twenty-four cases of infectious diarrhea, Bowditch examined the rectum and sigmoid by inspection. He found that cases of diarrhea in which there is a history of blood in the stools (especially among infants), show signs of inflammation (red, thickened mucous membrane, prominence of the follicles, ulcers of varying types, but no true membranous condition) throughout the sigmoid and rectum, especially during the acute stage of the disease. These lesions seem to vary according to the virulence of the infection as to number and general appearance. They gradually become healed, leaving no signs nor evidence of scar tissue visible to local sigmoidal inspection in life. Bowditch also found that blood and normal intestinal mucous membrane may be present at least in the sigmoid and rectum in cases of fermental diarrhea. Of the severer types of cases, all but two patients received *one* or more irrigations, three had four, and two received none. No sign of any healthy appearance was found, neither did the mucous membrane of those treated, or those untreated, differ in any appreciable way. Of these cases of milder type, all but two patients received silver nitrate irrigations. Three were given each a single irrigation early in the disease, five had more than two, and at the most, three irrigations. While a gradual improvement was apparent at the end of these repeated irrigations, at no time did the mucous membrane after a single treatment show any distinct betterment.

64. **Acute Lymphatic Leukemia in an Infant.**—The count in his case, which reached 1,330,000, is the highest leukocyte count which Veeder has been able to find on record in lymphatic leukemia in childhood. E. H., female, aged 17 months, was brought to the hospital for a purpuric eruption, which was said to have appeared five days before admission. Practically no history could be obtained. The child had been breast-fed. A swelling of the neck had appeared "some time" before the eruption. The skin was pale and showed a widespread purpuric eruption varying in size from small, bright red petechial spots about pinhead in size, to large subcutaneous extravasations, cyanotic in color, and about the size of a 25-cent piece. The large extravasations were present over the forehead, extensor surface of the forearms, the tibiæ, and over the spines of the lumbar vertebræ; the smaller lesions were most marked over the face, right shoulder and the legs. Pressure over the bones did not produce pain or signs of tenderness. The joints were uninvolved. The mucous membranes of the mouth were pale, but showed numerous points of hemorrhage. The saliva was slightly blood-streaked. The tonsils were large, swollen and red, almost shutting off the mouth cavity from the pharynx. The cervical lymph nodes were enlarged and palpable. They were moderately soft in consistency and about the size of a hickory nut. Pressure over the right side of the neck seemed to cause pain. The axillary and inguinal nodes were both enlarged and distinctly palpable as separate tumors about the size of lima beans.

The interesting feature of the case is the blood-examination: hemoglobin, 55 per cent.; erythrocytes, 3,370,000; leukocytes, 1,330,000. The field under the microscope was densely packed with lymphocytes, these being so numerous as practically to obscure everything else. The lymphocytes showed two distinct types, a small and a large cell variety, but between these two extremes there were so many gradations in size that an accurate subdivision of many of the cells into a large or small lymphocyte was impossible. The differential count (1,000 cells) was as follows: lymphocytes, 98.5 per cent.; polymorphonuclears, 1.2 per cent., and myelocytes, 0.3 per cent. One nucleated red cell was found during this count.

75. **Self-Medication.**—As a remedy for self-medication, the dangers of which are pointed out, Rice suggests that in view of the fact that each state has passed laws regarding the practice of medicine and pharmacy and as these laws were passed primarily for the protection of the people against ignorance and quackery and not for the protection of doctors and druggists, that these should be carried out and so amended and construed by the courts as to eliminate every form of quackery. Druggists should practice pharmacy, not medicine; they should refuse to indorse any patent or proprietary medicine; they should refuse to allow any nostrum to be advertised over their names; they should refuse to distribute booklets setting forth the many wonderful "cures," many of which are indecent and suggestive. Physicians should practice medicine, not pharmacy; they should prescribe, not dispense; they should prescribe drugs, not proprietary remedies, ready prepared under copyrighted names; the U. S. Pharmacopeia should be their guide; they should refuse to be "detailed" with copyright remedies or literature regarding them. The courts should clearly define the practice of medicine and what is meant by practice of pharmacy, and they should deny the right of those who are not duly qualified to practice either or to make a pretense thereto. Ready-made or proprietary remedies carrying directions and claiming to cure or mitigate disease should no longer be held by the courts to be mere merchandise, as the courts cannot regulate the claims made by the manufacturer. This narrow conception of justice allows the manufacturer, who in many instances is neither a physician nor a druggist, to diagnose by mail and practice medicine by wholesale. It allows the seller, regardless of his position in life, moral standard or qualification, to practice both medicine and pharmacy.

86 *Is Hemoglobinuric Fever a Manifestation of Malaria or a Disease *Sui Generis?* C. F. Craig, Washington, D. C.
87 *The Ventilation of Sleeping Cars. T. R. Crowder, Chicago.

81. **Spirilla of Relapsing Fever.**—In the circulating blood of a patient suffering from relapsing fever, Christian found spirilla on the second and third days of a three-day paroxysm of fever. These spirilla were inoculated successfully into monkeys and white rats. Both failed to show recurrence of the organism after the first infection. The lesion produced in monkeys consists of an accumulation of polynuclear leukocytes and endothelial cells in the sinusoids of the liver, and a focal infiltration of the spleen with polynuclear leukocytes. The spirilla appear to be removed from the circulation in the monkey by phagocytosis, to a slight extent in the liver, more actively in the spleen.

82. **Diphtheria Bacillus-Carriers.**—Pure culture of *Staphylococcus pyogenes aureus* sprayed in throats has, in seven cases, now reported, destroyed the Klebs-Loeffler bacilli in carriers in from forty-eight to seventy-two hours. Page adds one case and says that this method of treatment is harmless and should be used in all cases of carriers. It has been found useful immediately after convalescence from an acute attack. He suggests that it is probable that its use during an acute attack of diphtheria would be successful, but as yet it is inadvisable to attempt its use in any save mild acute cases. He also urges that a sanitary survey should be made after every diphtheria outbreak to eliminate carriers, whether they be human or animal. By animal inoculation a distinction should be made between the virulent and the "morphologic" carrier. Four negative daily cultures are necessary before quarantine is raised. Treatment of carriers has heretofore proven useless. Local measures, while necessary, fail to influence the virulence or duration of the bacilli. Antitoxin has no influence on the bacillus in a carrier.

83. **Study of Streptococci with the Complement-Fixation and Conglutination Reactions.**—The conglutination reaction in the authors' hands has not proved of much greater value in the differentiation of various strains of streptococci than the agglutination reaction. Although the conglutination and agglutination reactions are specific for streptococci, they are not specific for individual strains of streptococci. Their experiments, however, are not sufficient in number for definite conclusions on this point. They found that the best extract of streptococci for use as antigen in the complement-fixation test is that prepared by drying the washed organisms, grinding and shaking them for twenty-four hours. Immune bodies, specific for different strains of streptococci, can be demonstrated by means of the complement-fixation test. Swift and Thro suggest that it is possible by the use of this test we have a means of studying specific streptococcus infections.

84. **Examination of Cerebrospinal Fluid.**—In view of the fact that the technic employed for the examination of the cerebrospinal fluid varies greatly in the hands of the individual investigator and gives, in consequence, such discordant results, Bybee and Lorenz endeavored to develop a technic which shall have the advantages of uniformity and reliability, together with the simplicity requisite for ordinary bedside employment. Their technic differs from that of Fuchs and Rosenthal in that they employ a red-cell pipette, drawing the original stain to 0.7, and wiping away the excess of stain from the point of the pipette. The stain is then drawn up into the diluting-chamber in such a manner that it evenly coats the inner wall. They hold that the French or centrifuge method for examination of the cells in the cerebrospinal fluid is not reliable for numerous reasons: 1. The cells are not always entirely thrown down, even by prolonged centrifugation. 2. It seems probable that this failure may be due to the difference in density of cells and fluid being insufficient at all times. 3. It is impossible to collect in a pipette all the cells which are thrown down. 4. The centrifugation results in clumping of the cells, which cannot be entirely overcome. This method requires the use of a centrifuge and is consequently not clinical. The counting-chamber method, when modified so that the red blood cells do not stain, presents none of the above objections. It requires only the ordinary blood-counting apparatus. The amount of fluid necessary for the counting-chamber method is at a minimum. In their hands all clinically and cytologically positive cases of general paralysis of the insane gave a positive cell-chamber count. With the French method only sixteen positive results were obtained and twenty-four negative results. In connection with this point they call attention to the frequent statement in the literature that a single puncture is not reliable as a negative result, and that in none of their cases was more than one puncture used. Differential cell counts at present give but little additional information, except in so far as they distinguish a lymphocytosis from a leukocytosis. While this paper deals more especially with the cytologic problems, it is worth noting that Noguchi's butyric acid test gave thirty-eight positive results in forty clinically and cytologically positive cases of general paralysis of the insane.

85. **Schürmann's Color Test for Syphilis.**—While, in Owen's opinion a simple color test would be an ideal one, the method of Schürmann does not provide us with such a test.

86. **Hemoglobinuric Fever.**—That hemoglobinuric fever is not due to malaria Craig believes to be proved by its geographic distribution; by the fact that it occurs in individuals who have never suffered from malaria; and by the fact that, in many instances, neither before, during, nor after an attack can plasmodia be demonstrated in the blood; while even at

autopsy no trace of malaria can be found. That the disease is not due to quinin is proved by the fact that it occurs in individuals who have never taken the drug, and that in many regions where the drug is extensively used the disease is unknown. For the following reasons Craig believes that it is due to a specific organism: its geographic distribution; its numerical disproportion to malaria wherever it occurs; its occurrence in epidemics; the character of the pathologic lesions; its symptomatology; the lack of conclusive evidence that it is due to malaria; and its analogy with other well-known infectious diseases. He also calls attention to the peculiar relation that this disease apparently bears to the hemoglobinuric fever of cattle and to piroplasma infection in general.

87. **Ventilation of Sleeping-Cars.**—Even under the older applied principles of ventilation, the air-supply of sleeping-cars, as determined in Crowder's study, is ample under nearly all conditions. The average carbon dioxid in the air of running cars falls well within the limits of contamination permitted by the earlier investigators, and it is relatively rare that the individual observations show more than 10 parts in 10,000. In the light of the newer conceptions, which have as yet been applied in practice only to a very limited extent, this air-supply is ample under all conditions observed. No danger to health is to be apprehended under the conditions ordinarily obtaining even in still cars. They are occupied only for short periods as a rule and are not uncomfortable if kept cool. It would seem that the results obtained by the type of exhaust ventilator investigated by Crowder, which is now a part of the standard equipment of Pullman cars, are entirely adequate to meet the demands of hygiene, and that those difficulties and discomforts which do sometimes arise are due to other causes than lack of a sufficient amount of fresh air or to excessive vitiation. It is extremely unlikely that increasing the air-supply, which now amounts to from six to ten or more times the cubic content of the car each hour, and must maintain considerable motion of the atmosphere, would aid in any other way than by making overheating more difficult to bring about. Overheating is the paramount evil. It is the thing chiefly to be guarded against in the attempt to maintain comfort and good hygiene.

96 *The Construction of a Vagina. W. L. Wallace, Syracuse.

96. **The Construction of a Vagina.**—Wallace reports three cases. In one of these he pulled the mucous membrane of the vulva up to the cul-de-sac of Douglas, splitting the labia minora, making them single instead of double layers, and thereby getting longer mucous flaps. This made a vagina of mucous membrane the size and length of two fingers. In the other two cases he used intestine to make a vagina after the method of Baldwin. Hereafter, in using the ileum for the vagina, instead of bringing down the mi [illegible] stitching it to the vulva and opening it, af [illegible] Baldwin, Wallace says he would bring down [illegible] of the gut and sew them to the vulva, leaving [illegible] of the folded gut to form the roof instead of the entrance to the new vagina. This would save the necessity of closing and turning in the two ends, which procedure takes time and also uses up nearly an inch in length at each end. It also saves the necessity of opening the folded end to sew it to the vulva. This method would also make a smooth roof for the new vagina and would make the application of the clamp much easier, as the full length of the septum would be cut out. The intestine should be drawn down until the mesentery is taut, so that the new vagina will not prolapse; and any surplus mucous membrane should be cut away. Of course the mesentery must not be pulled down enough to interfere with the blood supply. Instead of using a Murphy button anastomosis of the divided sigmoid, Wallace prefers to tie a very large tube into the proximal end and then slightly invaginate the proximal into the distal portion of the gut, using fine silk to close the joint, and approximate the peritoneum, as suggested by Mayo, and as since used by Wallace in similar cases.

2. **Puerperal Eclampsia.**—Believing that the pregnant woman is protecting herself against a poison directly comparable to a venom, Murray suggests that there may be some therapeutic use for antivenin in eclampsia or the pre-eclamptic state. Judging from its action in snake poisoning, the likelihood of usefulness is very much greater in the latter.

4. **Cesarean Section for Dystocia.**—Routh calls attention to eight of these cases which, he believes, show that where ventrofixation causes dystocia, living children can be delivered with small risk to the mother by Cesarean section, after other attempts at delivery have been made, provided that antiseptic precautions have been carefully adopted. The only death was caused by a bowel complication present before the operation.

8. **Vaccines in Rheumatoid Arthritis.**—In two cases cited by Bannatyne and Lindsay, the results of serotherapy have been so satisfactory that they are encouraged to hope that in vaccines a cure may be found for many acute cases of rheumatoid arthritis. In both cases the micro-organisms were obtained from blood taken from veins of the antecubital fossa of the arm, after every precaution had been taken to ensure the impossibility of skin contamination. The media on which the cultures were obtained was blood-agar, and during the period of growth the incubator registered 35 C. In one case a growth was observed on the third evening, the appearance of the colonies being that of semi-transparent points. The appearance microscopically was that of a diplococcus, aggregated in clusters. The stain was retained after employing Gram's method. In the second case, a growth was observed on the second evening, in the form of single colonies less transparent than in the first case. These colonies became more abundant twelve hours later. Microscopically, the organism was found to be a micrococcus, arranged in clusters. The microorganisms were Gram-positive.

10. **Pitfalls of "Mental Tests."**—Myers urges extreme caution, at least for the present, in standardizing "mental tests" and in popularizing their use. He believes that in some forms, no doubt, tests can be usefully applied *en masse*—for example, with the object of determining the standard of intellect which a boy of given age should attain in order to class him as suitable or unsuitable to be taught in an "ordinary" or a "special" school. But, he says, such tests are "tests of production," not "mental tests." They determine how much an individual can work, how much he knows—not how he works, how he knows. A man's productivity, of course, is what we want to ascertain in every-day life. We do not care how a man comes to use or to acquire his powers; we are content with a mere dynamometric or other record of his powers. From this aspect, mass experiments must have some value. But this aspect cannot properly be called the psychologic aspect.

18 Atonic Dilatation of the Stomach. P. A. Mitchell.
19 Power of Speech in Cut-Throat. D. H. Metha.

12. **Auscultation of Joints.**—Garrod claims for auscultation of joints that this method is capable of affording early warning of troubles in articular structures and sometimes reveals the commencement of disease in joints, which to inspection and palpation appear to be normal, and which may even cause no discomfort to their possessor. Again, the method gives promise of help in the differentiation of articular diseases, and in distinguishing between those in which the cartilages and bones are implicated, and those in which the synovial membranes and soft parts around the joints alone suffer.

14. **Puerperal Convulsions.**—Thirty-nine cases are reported by Alexander: thirty patients were primiparæ and five multiparæ, in three the number of the pregnancy was unknown. In four cases the urine contained only a trace of albumin, and two of these proved fatal. In five cases the fits began before parturition set in; in five cases, during the first stage of labor; in six cases, during the second stage; in one case, in the third stage; in fifteen cases the attacks began postpartum, and in one case, Alexander has no clue to the time of onset. Of the postpartum onset, the times varied from a few minutes after the termination of the labor to as much as eight days after. In only five cases did the fits cease on delivery. Of the thirty-eight cases recorded, the mortality was 34.2 per cent. Alexander believes that the disease is very much on the increase, and that the mortality has increased very much in proportion.

The hastening of delivery was adopted in only seven cases. In five cases forceps were used, and one of these patients was suffering from pneumonia at the time and died from that disease. In one case artificial dilatation of the os and version effected the delivery of a decomposed fetus. The mother died suddenly, a few hours later, with a cardiac clot. In another transverse case the patient recovered after-delivery by version. The delivery was natural in twenty-nine cases. Two deaths occurred in seven cases of operative emptying of the uterus, or 28.5 per cent., and nine deaths in twenty-nine cases in which Nature was not interfered with, or 31 per cent. Routine treatment consisted of purgatives, such as jalap, magnesium sulphate, calomel and croton oil; diaphoretics, such as blanket bath, hot packs, pilocarpin, hot poultices over kidneys, saline diuretics, hot drinks; nerve sedatives, such as bromids, morphin, chloral in varied doses, fomentations to loin, dry cupping over kidneys, venesection of arm, ice to head and thyroid powder, chloroform and oxygen inhalations.

24. **Treatment of Cancer of Rectum.**—The ideal operation, according to Drummond, is one which removes the rectum and the lower iliac colon with the lymphatics, glands, and mesentery, and replaces the rectum by bowels drawn down from above through the anal sphincter. This, however, is seldom possible. In early cases, and with cancer high up without visible or palpable glandular infection, a more limited removal and anastomosis by the invagination method, is Drummond's operation of choice. In the ordinary case, permanent colostomy and an extensive abdomino-perineal operation offers the best chance of permanent success. In stout and muscular subjects, Kraske's operation is less dangerous than this, and the results, for the present, compare with it sufficiently favorably to justify its employment. The simpler perineal operations should be reserved for cases in feeble persons and those in whom the disease is limited to the neighborhood of the anus, or the anal canal. At the same time, or shortly after, the glands of both inguinal regions should be excised. Blood-loss, shock and sepsis may be minimized, and the perineal operation can be more rapidly completed, by leaving hemostatic forceps on the bleeding vessels, and using few or no sutures for the wound. Drummond says that further pathologic information is required, especially as to the direction in which the disease is most likely to spread, before more definite rules can be laid down for the treatment of cancer of the rectum. Colostomy, he declares,

autopsy no trace of malaria can be found. That the disease is not due to quinin is proved by the fact that it occurs in individuals who have never taken the drug, and that in many regions where the drug is extensively used the disease is unknown. For the following reasons Craig believes that it is due to a specific organism: its geographic distribution; its numerical disproportion to malaria wherever it occurs; its occurrence in epidemics; the character of the pathologic lesions; its symptomatology; the lack of conclusive evidence that it is due to malaria; and its analogy with other well-known infectious diseases. He also calls attention to the peculiar relation that this disease apparently bears to the hemoglobinuric fever of cattle and to piroplasma infection in general.

87. **Ventilation of Sleeping-Cars.**—Even under the older applied principles of ventilation, the air-supply of sleeping-cars, as determined in Crowder's study, is ample under nearly all conditions. The average carbon dioxid in the air of running cars falls well within the limits of contamination permitted by the earlier investigators, and it is relatively rare that the individual observations show more than 10 parts in 10,000. In the light of the newer conceptions, which have as yet been applied in practice only to a very limited extent, this air-supply is ample under all conditions observed. No danger to health is to be apprehended under the conditions ordinarily obtaining even in still cars. They are occupied only for short periods as a rule and are not uncomfortable if kept cool. It would seem that the results obtained by the type of exhaust ventilator investigated by Crowder, which is now a part of the standard equipment of Pullman cars, are entirely adequate to meet the demands of hygiene, and that those difficulties and discomforts which do sometimes arise are due to other causes than lack of a sufficient amount of fresh air or to excessive vitiation. It is extremely unlikely that increasing the air-supply, which now amounts to from six to ten or more times the cubic content of the car each hour, and must maintain considerable motion of the atmosphere, would aid in any other way than by making overheating more difficult to bring about. Overheating is the paramount evil. *It is the thing chiefly to be guarded against in the attempt to* maintain comfort and good hygiene.

96 *The Construction of a Vagina. W. L. Wallace, Syracuse.

96. **The Construction *of a Vagina*.**—Wallace reports three cases. In one of these he pulled the mucous membrane of the vulva up to the cul-de-sac of Douglas, splitting the labia minora, making them single instead of double layers, and thereby getting longer mucous flaps. This made a vagina of mucous membrane the size and length of two fingers. In the other two cases he used intestine to make a vagina after the method of Baldwin. Hereafter, in using the ileum for the vagina, instead of bringing down the middle of the gut, stitching it to the vulva and opening it, after the manner of Baldwin, Wallace says he would bring down the opened ends of the gut and sew them to the vulva, leaving the closed end of the folded gut to form the roof instead of the entrance to the new vagina. This would save the necessity of closing and turning in the two ends, which procedure takes time and also uses up nearly an inch in length at each end. It also saves the necessity of opening the folded end to sew it to the vulva. This method would also make a smooth roof for the new vagina and would make the application of the clamp much easier, as the full length of the septum would be cut out. The intestine should be drawn down until the mesentery is taut, so that the new vagina will not prolapse; and any surplus mucous membrane should be cut away. Of course the mesentery must not be pulled down enough to interfere with the blood supply. Instead of using a Murphy button anastomosis of the divided sigmoid, Wallace prefers to tie a very large *tube into the proximal* end and then slightly invaginate the proximal into the distal portion of the gut, using fine silk to close the joint, and approximate the peritoneum, as suggested by Mayo, and as since used by Wallace in similar cases.

8 *Treatment of Rheumatoid Arthritis by Vaccines. G. A. Bannatyne and J. Lindsay.
9 The Proposed Coroner's Bill. J. Griffiths.
10 The Pitfalls of "Mental Tests." C. S. Myers.

2. **Puerperal Eclampsia.**—Believing that the pregnant woman is protecting herself against a poison directly comparable to a venom, Murray suggests that there may be some therapeutic use for antivenin in eclampsia or the pre-eclamptic state. Judging from its action in snake poisoning, the likelihood of usefulness is very much greater in the latter.

4. **Cesarean Section for Dystocia.**—Routh calls attention to eight of these cases which, he believes, show that where ventrofixation causes dystocia, living children can be delivered with small risk to the mother by Cesarean section, after other attempts at delivery have been made, provided that antiseptic precautions have been carefully adopted. The only death was caused by a bowel complication present before the operation.

8. **Vaccines in Rheumatoid Arthritis.**—In two cases cited by Bannatyne and Lindsay, the results of serotherapy have been so satisfactory that they are encouraged to hope that in vaccines a cure may be found for many acute cases of rheumatoid arthritis. In both cases the micro-organisms were obtained from blood taken from veins of the antecubital fossa of the arm, after every precaution had been taken to ensure the impossibility of skin contamination. The media on which the cultures were obtained was blood-agar, and during the period of growth the incubator registered 35 C. In one case a growth was observed on the third evening, the appearance of the colonies being that of semi-transparent points. The appearance microscopically was that of a diplococcus, aggregated in clusters. The stain was retained after employing Gram's method. In the second case, a growth was observed on the second evening, in the form of single colonies less transparent than in the first case. These colonies became more abundant twelve hours later. Microscopically, the organism was found to be a micrococcus, arranged in clusters. The microorganisms were Gram-positive.

10. **Pitfalls of "Mental Tests."**—Myers urges extreme caution, at least for the present, in standardizing "mental tests" and in popularizing their use. He believes that in some forms, no doubt, tests can be usefully applied *en masse*—for example, with the object of determining the standard of intellect which a boy of given age should attain in order to class him as suitable or unsuitable to be taught in an "ordinary" or a "special" school. But, he says, such tests are "tests of production," not "mental tests." They determine how much an individual can work, how much he knows—not how he works, how he knows. A man's productivity, of course, is what we want to ascertain in every-day life. We do not care how a man comes to use or to acquire his powers; we are content with a mere dynamometric or other record of his powers. From this aspect, mass experiments must have some value. But this aspect cannot properly be called the psychologic aspect.

17 Subluxation of the Knee. J. J. W. Evans.
18 Atonic Dilatation of the Stomach. P. A. Mitchell.
19 Power of Speech in Cut-Throat. D. H. Metha.

12. **Auscultation of Joints.**—Garrod claims for auscultation of joints that this method is capable of affording early warning of troubles in articular structures and sometimes reveals the commencement of disease in joints, which to inspection and palpation appear to be normal, and which may even cause no discomfort to their possessor. Again, the method gives promise of help in the differentiation of articular diseases, and in distinguishing between those in which the cartilages and bones are implicated, and those in which the synovial membranes and soft parts around the joints alone suffer.

14. **Puerperal Convulsions.**—Thirty-nine cases are reported by Alexander: thirty *patients were primiparæ and five multiparæ*, in three the number of the pregnancy was unknown. In four cases the urine contained only a trace of albumin, and two of these proved fatal. In five cases the fits began before parturition set in; in five cases, during the first stage of labor; in six cases, during the second stage; in one case, in the third stage; in fifteen cases the attacks began postpartum, and in one case, Alexander has no clue to the time of onset. Of the postpartum onset, the times varied from a few minutes after the termination of the labor to as much as eight days after. In only five cases did the fits cease on delivery. Of the thirty-eight cases recorded, the mortality was 34.2 per cent. Alexander believes that the disease is very much on the increase, and that the mortality has increased very much in proportion.

The hastening of delivery was adopted in only seven cases. In five cases forceps were used, and one of these patients was suffering from pneumonia at the time and died from that disease. In one case artificial dilatation of the os and version effected the delivery of a decomposed fetus. The mother died suddenly, a few hours later, with a cardiac clot. In another transverse case the patient recovered after delivery by version. The delivery was natural in twenty-nine cases. Two deaths occurred in seven cases of operative emptying of the uterus, or 28.5 per cent., and nine deaths in twenty-nine cases in which Nature was not interfered with, or 31 per cent. Routine treatment consisted of purgatives, such as jalap, magnesium sulphate, calomel and croton oil; diaphoretics, such as blanket bath, hot packs, pilocarpin, hot poultices over kidneys, saline diuretics, hot drinks; nerve sedatives, such as bromids, morphin, chloral in varied doses, fomentations to loin, dry cupping over kidneys, venesection of arm, ice to head and thyroid powder, chloroform and oxygen inhalations.

24. **Treatment of Cancer of Rectum.**—The ideal operation, according to Drummond, is one which removes the rectum and the lower iliac colon with the lymphatics, glands, and mesentery, and replaces the rectum by bowels drawn down from above through the anal sphincter. This, however, is seldom possible. In early cases, and with cancer high up without visible or palpable glandular infection, a more limited removal and anastomosis by the invagination method, is Drummond's operation of choice. In the ordinary case, permanent colostomy and an extensive abdomino-perineal operation offers the best chance of permanent success. In stout and muscular subjects, Kraske's operation is less dangerous than this, and the results, for the present, compare with it sufficiently favorably to justify its employment. The simpler perineal operations should be reserved for cases in feeble persons and those in whom the disease is limited to the neighborhood of the anus, or the anal canal. At the same time, or shortly after, the glands of both inguinal regions should be excised. Blood-loss, shock and sepsis may be minimized, and the perineal operation can be more rapidly completed, by leaving hemostatic forceps on the bleeding vessels, and using few or no sutures for the wound. Drummond says that further pathologic information is required, especially as to the direction in which the disease is most likely to spread, before more definite rules can be laid down for the treatment of cancer of the rectum. Colostomy, he declares,

is never fair treatment of cancer of the rectum, and should be reserved only for cases in which there is definite obstruction or for the relief of fistulous openings.

26. **Treatment of Plague.**—Thomson's remarks are founded on an extensive personal experience of the disease in Hong Kong. Speaking first of the general management of a case of plague, he says that while pneumonic plague is a highly infectious disease requiring the strictest isolation, bubonic and septicemic plague (far commoner than the pneumonic type) is not infectious, and might safely be treated in the wards of general hospitals or in the patients' own homes. When plague prevails, the extermination of rats is of primary importance; the methods of doing so which have proved most efficacious are traps and poisons. During the illness, the disinfection required is very much the same as in a case of typhoid. Nurses should be warned of the possibility of infection through an abrasion of the skin, and any abrasions present ought to be protected by collodion. Alcoholic stimulant (4 oz. of brandy daily) is generally required, and cardiac stimulants, digitalis, strychnin, strophanthus, are constantly required. The disease is essentially an asthenic fever. It is also important to attend to the bladder, as retention of urine is common, and to cleanse the mouth.

According to Thomson there is no really satisfactory specific treatment for plague, and for the most part, symptomatic treatment is an essential feature. As to the specific methods of treating the disease, Thomson relates his experiences with carbolic acid, given in large doses—12 gr. every two hours, or 144 gr. daily. If the drug was pure, carboluria rarely occurred, and when it did, all that was necessary was to intermit a few doses. He has treated a series of 143 patients in this way, with a mortality of 30 per cent. In Hong Kong the mortality of cases in which serotherapy was used was 80 per cent.; in Oporto, 14 per cent.; in Brisbane, 40 per cent. In India, taking selected cases, the mortality had been reduced from 74 to 63 per cent. by the use of the Yersin and Roux serum, and in private cases to 40 per cent. In Hong Kong, Thomson has never had such good results, though employing the same serum. Haffkin's prophylactic is of great value, he asserts, and should be given to nurses and contacts; it prevents the disease, even if given during the inoculation period. The third line of specific treatment is by organotherapy. Epinephrin is said to have reduced the mortality to 37 per cent. in a reported series of cases, and the success was enough to warrant further trial.

37 Twenty-Five Cases of Epidemic Meningitis. R. Voisin and G. Paisseau.

35. **Subscapular Friction Sounds.**—A friction sound or cracking under the scapula when the shoulder is moved has been regarded as a sign of something wrong in the bone or periosteum but Tedeschi, in 1908, called attention to it as a sign of a tuberculous lesion in the lung below, and still more recently Rénon stated that it has considerable diagnostic importance for differentiation of pulmonary tuberculosis. Laroquette has been studying it on an extensive scale, examining 824 different individuals, including 161 with various diseases, mostly tuberculosis, and 43 children. He found the sounds pronounced in 8.2 per cent. of the 620 healthy persons examined; in 18.6 per cent. of the sick, and only once in a child. He also had occasion to examine post mortem several individuals who during life had had the sound very distinct. In his eighty-two cases with positive findings, the sounds were audible on both sides in forty. From this experience he concludes that the sound in itself has absolutely no pathologic importance; it is similar to the cracking sound heard sometimes in other joints as they are moved although the joints are and remain apparently healthy. The sounds are the result of contraction of certain muscles; when the joint is moved passively there is no sound. After the individual's attention is once attracted to the sound he notices it as he moves his shoulder and is liable to grow uneasy about it and imagine sensations in the joint. When the sounds are detected in a person who has never noticed them particularly, the physician should refrain from calling attention to them. The nervous system should be given general treatment if necessary.

36. **A Sarcoma of the Medulla Oblongata.**—At necropsy a sarcoma as large as a walnut was found in the medulla oblongata, entailing inflammation and atrophy of the cerebellum. The main complaints had been difficulty in swallowing and pain in the back of the neck. The first symptoms had been observed four years before. The velum was paralyzed and a sudden attack of dyspnea developed in which the patient succumbed. In a second case, death occurred suddenly after a week or so of symptoms diagnosed in the hospital as cerebrospinal meningitis. In ninety-two cases of tumors in the medulla oblongata on record, they proved to be sarcomas in only seventeen instances. These patients were between the ages of 25 and 40 and were mostly women, and the tumor was primary, without metastasis. Such tumors compress and destroy the nervous elements; they do not diffuse but remain well circumscribed. The first signs of trouble come on abruptly and the syndrome develops by repeated exacerbations, death occurring generally suddenly from action on the cardiorespiratory centers. Secondary hemorrhages are liable to occur in the growth. The profound destruction and successive involvement of the different bulbar nuclei induce a clinical picture very different from that of glioma; this wealth and multiplicity of the symptoms give the clue to the nature of the tumor, no other tumor in the medulla revealing its presence so unmistakably.

45 Research on Antispermotoxic Serums. J. G. Fitzgerald.

42. **Prophylaxis of Accidents in Serotherapy.**—Besredka and Lissofsky state that recently in Paris alone there have been ten deaths which they ascribe to injection of antimeningococcus serum into the spinal canal. Hutinel has recently also called attention to four fatalities after intraspinal injection of the serum. Their experimental research has shown, however, that the phenomena of anaphylaxis to which they ascribe these accidents can be prevented by fractioning the serum to be injected. Their experimental research has shown that vaccination with repeated minute doses is borne by the guinea-pigs, while it is rapidly fatal if the vaccine is given in a single dose. They found that every guinea-pig sensitized by subcutaneous injection of a serum reacts with anaphylaxis when a new injection of the same serum is made into the spinal canal. However, there are no signs of anaphylaxis if the serum is fractioned in minute doses, whether administered by way of the skin, peritoneum, spine or veins. This occurs most rapidly with intravenous vaccination and most slowly with the subcutaneous; immunity is obtained with the intravenous route in fifteen minutes, while with the subcutaneous four hours are required. The antianaphylactic immunity thus acquired, after vaccination by the spinal route, does not last over twelve or fifteen days. They describe a number of series of experiments: For instance, a guinea-pig

weighing 420 gm. was vaccinated with 0.5 c.c. of serum injected into the jugular vein. Ten minutes later 0.14 c.c. was injected into the spinal canal. No signs of disturbances were observed although this is a rapidly fatal dose for unvaccinated guinea-pigs. The absolute protection against anaphylaxis was thus complete in ten minutes with the intravenous technic. An untreated animal given an intraspinal injection of the serum is sure to show signs of fatal anaphylaxis if another injection is made.

56. **Treatment of Varices on the Legs.**—Moro reports forty-two patients with serious varicose disturbances all entirely cured by operative treatment according to Novaro's technic. This aims to interrupt the pathologic reflux of venous blood from the deep into the superficial veins which is the cause of the trouble. This pathologic reflux may occur solely at the point where the saphena magna empties into the femoral vein, or the intercommunicating veins may be involved in the valvular insufficiency between the deep and the superficial systems of veins. Any operative measure which acts merely on the superficial veins does not attack the real source of the trouble. Resection of the saphena magna at its junction with the femoral vein answered the desired purpose in full in 44 per cent. of his forty-two cases; in the others this operation had to be supplemented by resection of one or more of the intercommunicating veins. He tabulates the details of his cases and reports research on the cadaver which demonstrated that sudden violence was unable to force the valves to a point to induce varices; long-continued action of the injurious influences was necessary for this. He concludes his article by urging prompt intervention without waiting for the varicose disturbances to become very pronounced. In the early stages the Trendelenburg method of resecting the saphena magna at its junction with the femoral vein will cure the tendency permanently and prevent extension of the trouble to the intercommunicating veins.

69 Radiology of the Stomach. (Ein Wort über den Wismutmagen.) B. Stiller.

62. **Polycythemia.**—Stachelin reports that he has encountered seven pure cases of polycythemia with abnormally high blood-pressure and four others complicated with emphysema, heart defect, arteriosclerosis or nephritis—all in the course of one year. There was a history of syphilis in only one case. Permanent improvement or cure was not observed in any instance. He tabulates the various details for comparison and states that differentiation has not been of much use so far as treatment is concerned, as no measures gave permanent benefit, but yet differentiation is important on account of the prognosis. This is much more unfavorable than for neurasthenia, with which the disturbances might be confounded, or the patient might be accused of exaggeration or malingering. In the severe cases all the visible veins are turgid and the skin and mucosa are a cyanotic red, redder than with cyanosis and emphysema. The majority of the patients looked like healthy persons just after a hearty meal or severe muscular exercise. In the milder cases the patients' complaints had invariably been ascribed to neurasthenia.

63. **Dietetic Treatment of Kidney and Heart Disease.**—Levy regards an exclusively milk diet as essentially a salt-poor diet, but he warns that large amounts of milk contain appreciable quantities of salt. He gives a number of examples to show the great efficacy of prolonged prohibition of salt in treatment of severe parenchymatous nephritis with rebellious dropsy; two such patients had previously been systematically treated for six months with all other measures without improvement. He then put them on a mixed diet free from salt and in two months the dropsy had vanished. During this time one patient eliminated 300 gm. of salt; at first the kidney had not been permeable for salt, but in the course of the three weeks in which the kidney had been relieved of the task of salt elimination, it recuperated so that it eliminated constantly more and more, accompanied by the water to hold it in solution, and by the second month this patient's weight had declined by 66 pounds. This patient had not taken over 2 or 3 gm. of salt daily in the food during this period. If the restriction had been less severe and less systematically carried out, so that 5 or 6 gm. of salt a day had been permitted, the patient probably would never have been relieved of the dropsy. These cases not only emphasize the efficacy of the salt-poor diet after failure of all other measures, but they show the long course of the treatment necessary. Kidney patients of this class do not lose the dropsy so fast as patients with heart disease. The salt-poor diet may be valuable also with cirrhosis of the liver and heart disease although the mechanism of its action is different in such cases, the benefit being due to improvement in the conditions in the circulation as the superfluous salt is dropped from the diet. Reduction of the intake of albumin may also prove useful, as it spares the kidneys extra work. Restriction of fluids may prove efficient but only indirectly, as the patients unconsciously limit the intake of food and especially of salty foods, to prevent thirst when they are not allowed to drink water freely.

64. **Venesection and Saline Infusion in Treatment of Skin Diseases.**—Bruck has been treating eight patients with various skin affections by venesection, withdrawing about 250 c.c., following this with intravenous infusion of 500 c.c. of physiologic salt solution, his aim being to wash out the toxins in the blood which he regards as responsible for the skin disease. The effect was favorable in generalized pruritus, urticaria, erythema multiforme with effusion, and herpetiform dermatitis; no effect was observed in psoriasis and in a case of

diffuse eczema. This "lavage of the blood" not only washes out toxins but stimulates the blood-producing organs, and he thinks that it is liable to prove useful in a number of other skin affections in which the action of toxins may be assumed as a factor.

65. **Landry's Paralysis.**—Bolten reports two cases of typical paralysis of the Landry type, both confirming the assumption that the paralysis is the result of intoxication of the spinal cord, the action of the toxin interfering with the functioning of the spinal and bulbar centers, while it is not sufficient to be actually destructive. The toxins seem to leave the sensory neuron intact and merely to check motor functioning. Treatment of one patient on this hypothesis resulted in a complete cure. The aim was to substitute the cerebrospinal fluid by a non-toxic fluid; this was accomplished by withdrawing small amounts of the spinal fluid and replacing it with the same amount of physiologic salt solution. This was done six times in the course of eight days in the case reported —a total of 600 c.c. of spinal fluid being withdrawn and 540 c.c. of a salt solution being injected. The patient was a previously healthy young man, but for days the severe bulbar symptoms, extensive bronchitis and total paralysis of the diaphragm, vocal cords and muscles of swallowing rendered the prognosis very grave. The paralysis subsided in the various muscles in reverse order to its development, and the patient was dismissed in good condition after five weeks. In the first case there were signs of severe intestinal autointoxication and transient improvement followed calomel, but the patient died the tenth day.

66. **Serious Disturbances After Preventive Serotherapy.**—Allard remarks that the disturbances known commonly as "serum sickness" have been observed mostly in children and have been comparatively harmless, but he has recently encountered two cases in which almost fatal accidents developed after a preventive injection of antianthrax serum from a sheep or antitetanus horse serum. Both patients were physicians; the first had been inoculated with antitoxin for diphtheria seven years before and again a year and a half later. Four years after this he had also been immunized against rabies, being given at this time twenty-one subcutaneous injections of rabbit antirabies virus. He had thus been injected on two occasions with horse serum and then with rabbit virus, and when injected with the sheep serum he responded with typical anaphylactic phenomena just as in a laboratory experiment. The second patient had been given antitoxin treatment for diphtheria in 1898 and again in 1904, and he reacted to the injection of antetanus serum with intense general symptoms a few hours later, recurring in exacerbations during the week; the syndrome finally terminated with the severest attack on the eighth day, after which the pulse and respiration soon returned to normal. Other patients injected at about the same time with the same serum showed no disturbance. Treatment was in both cases by injection of camphor and caffein or drinking strong coffee. The urine was normal in both cases during and after the collapses. The prompt and complete recovery after the severe manifestations was a striking feature of the case. Allard reviews in conclusion what others have written on the subject, and comments that he did not dare, in the serious syndrome observed, to follow Besredka's suggestion to give ether; Besredka found that the animals in experimental anaphylaxis all survived when deeply anesthetized with ether. Allard commends the suggestion to use antitoxins made from different animals and in as concentrated form as possible.

68. **The Tryptophan Test for Gastric Cancer.**—Ley applied this test in twenty cases, all with anacidity, and twelve suggesting cancer. The findings were contradictory; in the four certain cases of cancer a positive reaction was obtained only in two, while the findings were also positive in four cases of simple gastric catarrh.

70 Salvarsan in Syphilis. B. Bloch.
71 *Recurring Hypertrophy of the Prostate After Prostatectomy. [illegible]
72 *Alkaptonuria. A. Oswald.

71. **Recurring Prostatic Obstruction After Prostatectomy.**—The disturbances from enlargement of the prostate in the case reported were practically cured by castration and cure of the cystitis but they returned again after five years, at which time perineal prostatectomy was done. Only a few scraps of the prostate were left, but they proliferated again in the course of three years until fatal uremia resulted. In this, as in two other cases previously reported from the same clinic there was no sign of a malignant tendency, the prostate tissue merely seemed to be endowed with an exceptional faculty for pure proliferation. The prostatectomy had been regarded as "total" in all these cases.

72. **Alkaptonuria.**—Oswald has found only sixty cases of alkaptonuria on record and he believes that it often escapes recognition as it must be more frequent than the literature would suggest. He compares it with diabetes and thinks that closer study of alkaptonuria might throw light on diabetes and other constitutional taints. He consequently urges physicians to be on the lookout for it and to report their cases or inform him personally of the details. The anomaly is easily recognized by the brown discoloration of the urine when it is shaken up for two or three seconds in a test-tube after it has been rendered alkaline by addition of solution of sodium or potassium hydroxid. The alkaptonuric urine has also reducing properties, giving the Trommer reaction.

82 Improved Technic for Pubiotomy. (Zur Technik der Hebosteotomie: Die Beckienklammer, ein neues Instrument.) E. Blos.

74. **Double Induced Pneumothorax.**—Forlanini reports two cases in which after one lung had healed under an artificially induced pneumothorax, he applied the same procedure to the other lung, and with equal success. He also adds the histories of two other cases in which conditions would permit the making of a second pneumothorax on this or the other side in case such an operation ever becomes necessary. His cases confirm, he asserts, the reliability of this means of treating pulmonary lesions and its efficacy. Results are naturally better the earlier treatment is applied, and his experiences, he thinks, justify its application even for incipient lesions. Scrupulous care must be exercised to prevent infecting the pleura; if pleurisy develops adhesions form which interfere with the pneumothorax.

76. **Salvarsan in Chorea.**—The case reported is cited as an instance of successful treatment of recurring chorea minor with salvarsan. The patient was a girl of 8, and the severe chorea subsided in the course of the four weeks following the injection; but the patch of necrosis at the site of the subcutaneous injection near the costal arch had shown no signs of healing although it had ceased to spread by the end of this time. It was a little smaller in size than a silver quarter.

78. **Fate of Salvarsan in the Body.**—Bornstein has examined several cadavers of individuals dying of intercurrent affections from two weeks to several months after injection of salvarsan. The findings harmonized with those obtained in his research on rabbits, all showing that the arsenic injected in the form of salvarsan is carried to the liver, kidneys and spleen and stored up there, not only when it is incorporated by the intravenous route but also when injected into the muscle or subcutaneous tissue. It circulates in the blood only for a comparatively brief time. He found in one cadaver two weeks after injection 6.5 mg. of arsenic in the liver; 3.1 mg. in the kidneys, and 1.8 mg. in the spleen.

79. **Epidemic Poliomyelitis.**—Eckert analyzes nineteen cases of acute poliomyelitis in his charge at Berlin. Besides the paralysis, the pain in the spine and the profuse sweats were

the predominant features. One of the patients had had the same disease in 1903, leaving paralysis of the left leg, requiring later tenotomy. In 1909, the second attack occurred; it left the right leg paralyzed. One child of 8 died the eighth day of the disease which had developed with a fulminating course. He witnessed benefit in one case at least from lumbar puncture. He also made a point of mercurial inunctions during the acute phase, with hot baths and sweats, for their antiphlogistic action; electricity was used after subsidence of the pain in the spine. The Wassermann reaction was constantly negative with the cerebrospinal fluid, but a weak reaction was obtained with the blood in four out of the five cases tested.

80. **Sciatica Complicated with Scoliosis.**—Plate gives twenty-three illustrations of seven patients with chronic sciatica who also presented a greater or less tendency to scoliosis. He analyzes the cause of this tendency and explains it as the result of propagation of the trouble in the root of the sciatic nerve to the lumbar plexus with resulting neuralgia of the sensory nerve fibers in the muscles in the iliac region. On account of this pain these muscles are not normally stretched and in consequence the hip joint is slightly flexed; this shortens the leg and tilts the pelvis, the latter compelling curvature of the spine to maintain the balance of the body. The practical point is that the myalgia of the iliacus and psoas muscles requires treatment along with the sciatica in cases complicated with scoliosis.

97 *Improved Technic for the Antitrypsin Test. (Platten für die Trypsinprobe.) Kniaskof.

93. **Diphtheria Bacillus-Carriers.**—Kretschmer states that the diphtheria bacilli often lurk in the recesses of the tonsils long into convalescence, and he has succeeded in freeing thirteen patients from them by crushing the tonsils, thus squeezing out the plugs and secretions. He did this from one to nine times in the different cases, finally freeing the diphtheria convalescents in this way in from seventeen to thirty-eight days after the commencement of the disease. The results were promptest with the more accessible tonsils, more repetitions being necessary when the tonsils were far back.

97. **The Antitrypsin Test.**—Kniaskof extols the advantages of using gelatin instead of the Loeffler plate. He pours 10 or 15 c.c. of a 10 or 15 per cent. gelatin solution into a Petri dish and after it is hardened, he covers it with a 10 per cent. solution of formalin. After from twelve to twenty-four hours the formalin is poured off and the plate is rinsed for an hour under running water and then dried with blotting paper. Plates thus prepared kept for a long time. The little dimples formed from the eating away by the fluid to be examined, show up better if the gelatin is stained with a few drops of India ink while it is fluid. Scraps of the stained gelatin can also be used to test the fluid by dropping them into it. If the gelatin is dissolved by the action of the trypsin the fluid becomes stained by the India ink. No change of tint is accepted as a positive reaction to the antitrypsin test. [This test was described in The Journal, July 4, 1908, page 83.]

103 Ovarian Dermoids. (Zur Aetiologie der Ovarialdermoide und zur Kenntnis der darin vorkommenden Haare.) M. Yamasaki.

98. **Extraperitoneal Cesarean Section and Pubiotomy.**—Döderlein has done Cesarean section by the extraperitoneal route in thirty-two cases by the technic which he describes and illustrates. The extraperitoneal slanting incision in the inguinal region is made with the patient's shoulders very low, but when ready to extract the child, the pelvis is lowered. All except three of the women were safely delivered. One of these succumbed to eclampsia twelve hours later and another was seriously septic when first seen after four days of labor; her child was dead, and another child could not be revived. Paralytic ileus was responsible for the third fatality. The great disadvantage of this technic is that it is more difficult to extract the child, but this is overbalanced by the advantages of not opening into the peritoneum and the less subjective discomfort for the patient. He has performed pubiotomy in fifty-three cases with the loss of only one patient from paralytic ileus. This operation has a mortality to date of six in 321 cases at seven large clinics, that is, 1.8 per cent. The two operations do not compete with but supplement each other. With manifest infection both are contraindicated.

100. **Vaginal Methods for Gynecology.**—Dobbert reviews his experience with the vaginal technic at St. Petersburg with or without supplementary laparotomy. The lesson taught, he says, is that the rational combination of the vaginal and abdominal methods is the technic for the future.

101. **Acute Dilatation of the Stomach.**—Hellendall reports four recoveries, that is, 53.54 per cent. of his total material. He has compiled 140 cases from the literature, including eighty-six in which the dilatation followed an operation. The list includes thirty-nine cases of dilatation of the stomach after gynecologic operations and twelve after gall-stone operations. An important symptom is the explosive vomiting with long intervals of comparative well being; the stomach region protrudes while the rest of the abdomen is not distended nor rigid. He ascribes the trouble in one of his cases to propagation of an infectious process in the small pelvis to the stomach wall, entailing atony. In a second case the dilatation was the result of accumulation of gases and they escaped as the tube was introduced; there was no abdominal infection in this case. In another case the vomiting was more like regurgitation, the mouth filling at brief intervals and the patient merely spitting out the fluid. The rapid pulse and difficulty in breathing are the main symptoms. In three of his cases the history was suspicious of old gastric ulcer. The dilatation may be primary or secondary; treatment should aim to tone up the stomach walls and to relieve it of its accumulated contents. It is especially important to repeat the gastric lavage at the moment when the paralyzed stomach begins to become distended again. The most certain prophylaxis of trouble is prevention of great distention of the upper abdomen, keeping up the patient's strength with nutrient enemas, saline infusion and subcutaneous injections of camphor or sugar solution. Desguin recommends specific serotherapy when infection is responsible for the dilatation. If the lavage of the stomach does not remedy conditions, the patient should be placed in the ventral decubitus to act on the occlusion of the duodenum probably responsible for the symptoms. Schnitzler has cured patients in this way. Bäumler commends the knee-chest position but notwithstanding the twenty successful cases on record in which this has been done, some writers regard it as dangerous—*Borchardt* has

reported a fulminating aggravation of the disturbances. Special care is necessary for patients after laparotomy, and Hellendall thought that one of his patients was injured rather than benefited by the position treatment.

106. **Otologic Findings After Injection of Salvarsan.**—Beck has examined over a hundred syphilitics after salvarsan treatment; the findings confirm the fact that changes in the internal ear may be observed after taking the drug. All the patients examined had been referred to the university otologic clinic in charge of Urbantschitsch, on account of complaints in regard to their ears. In one case an otitis media, rebellious to all treatment for several months, healed completely nine days after injection of the salvarsan. In three other cases both the labyrinth and vestibule were evidently affected, the symptoms not coming on until five, *seven and nine weeks after* the injection of salvarsan; the Wassermann reaction was negative. None of these patients had ever had attention attracted to the ears before. There had been little change for the better in these patients during the three weeks to date of writing. The syndrome in one case was that of typical Menièreiform cerebral polyneuritis. In another case the vestibular nerve was alone affected without any subjective vestibular symptoms and there has been no change to date; the symptoms developed four months after the injection of the salvarsan and have remained unmodified to date. Beck thinks that this case speaks for a toxic action of the drug on the vestibular nervous apparatus similar to that which Rothig found in mice after treatment with arsacetin. Symptoms like those presented by this patient have been observed in untreated syphilis, but they almost invariably show a decided tendency to retrogression while in the case reported they have persisted. He knows, however, of a similar persisting syndrome in a case in which no salvarsan had been given. He adds that ear affections in untreated syphilis are comparatively rare while they have become unusually common since the introduction of salvarsan. The syndrome observed in his cases was like that in Rille's three patients developing over ten and twelve weeks after the injection [mentioned in THE JOURNAL, January 28, page 311]. Beck thinks it probable that persons whose ears are not entirely intact before taking the salvarsan are more liable to develop these nervous symptoms in the organ of hearing.

107. **Prognosis of Puerperal Psychoses.**—Jolly has been able to trace to date, after an interval of ten years at least, seventy-nine patients with puerperal psychoses at the Halle university clinic for nervous and mental diseases, 1887-1900. Complete recovery was observed *only in 46 per cent.* with slight change in character in an additional 13 per cent. In twenty-six of the seventy-nine there was recurrence of the psychoses—in fifteen in connection with other pregnancies. Only two of the nine patients recovered whose psychosis developed during pregnancy; twenty-nine of the fifty-five with true puerperal psychoses, and five of the fifteen whose psychoses developed during lactation. Six of the seven patients with mania recovered completely; the other patient died. Half of the six patients with catatonia developed dementia later, one after an interval of eight years of health. The best outcome was in the twenty-eight cases of amentia, complete recovery following in nineteen after an interval ranging from five weeks to eighteen months, and complete recovery in two others after an intercurrent recurrence. In four cases the amentia progressed to dementia. The amentia developed almost exclusively during the puerperium. In 25 per cent. of the puerperal cases there had been infection.

109. **Influencing Shape of Skull in Infants.**—THE JOURNAL summarized recently Walcher's views in regard to the necessity for watching over the way an infant lies in order to mould its head into normal shape and outline. Avoidable deviations from normal shape are frequently responsible for traction on important tissues within the skull and resulting brain trouble. He here relates further experiences in this line and the results of position in correcting abnormal tendencies. When deemed necessary to have the child lie on its back, he uses a low crib with high walls which the child cannot see through, and it lies on its back to look up. To keep the child on its side, the crib is made with lattice-work walls and is placed on a table against the wall, so that the babe has to lie on its *side to watch what is going on.* The pictures of twins "before and after" show the great differences in the shape of the skull that can be realized by the mere position of the crib and whether the child can look through its walls or not.

114. **Apocynum Cannabinum in Chronic Heart Disease.**—Fehsenfeld reports satisfactory experiences with Canadian hemp in a number of cases of chronic cardiac insufficiency in which digitalis had failed. The action is *similar to that* of digitalis though not so durable; the hemp extract therefore may prove useful when digitalis is contra-indicated or has worn out its usefulness.

120. **Salvarsan in Syphilis.**—Ehrmann has given this drug to *eighty syphilitics* in the last five months and he has noticed that the syphilids which develop thereafter differed from those usually observed at the stage of the disease involved and to such an extent as to suggest that the organism was modified in some way by the medication. In *one* case toxic action on the organ of hearing was manifest, the troubl in the auditory nerve developing in the fourth month of the disease, two months after injection of salvarsan which had been followed by sloughing at the point of injection. Improvement followed excision of the gangrenous mass; in 5.69 gm. of the gangrenous tissue he recovered 0.0032 gm. arsenic and he thinks it probable that in the gangrenous tissue some chemical transformation of the drug had occurred rendering it more toxic. He had two syphilitic patients in former years who became hard of hearing, with tinnitus, under mercurial treat-

ment alone, but under continued intermittent mercurial treatment these symptoms finally subsided. He ascribes the disturbances in the ear in part to the Herxheimer reaction, in part to the syphilitic process itself, and in part to the direct action of the mercury or salvarsan, but believes that it is more liable to occur in the cases with local infiltration or gangrene on account of the possible chemical transformation of the salvarsan in tissues of this kind. Abuse of tobacco or other factor causing a predisposition on the part of the auditory nerve is liable to cooperate in the production of such symptoms.

121. **Roentgen-Ray Research on Absorption of Mercury and Salvarsan.**—Ullmann and Haudek report the results of extensive research in this line which emphasize the advantages of fractioning the salvarsan so as to inject it in minute doses at several points at once; only a small proportion of a large dose seems to be completely absorbed and the unabsorbed portion is a menace to the tissues.

122. **Early Diagnosis of Gastro-Intestinal Cancer by Meiostagmin and Hemolytic Reactions.**—Kelling reports distinct positive reactions in 47 per cent. of forty-five patients with cancer tested for the meiostagmin reaction while positive findings were obtained in only three of eighty-five patients with non-malignant affections. The reaction was obtained in some of the cancer cases before a tumor was palpable, testifying to the importance of the test for the diagnosis of incipient cancer. He also applied the hemolytic test with hen blood-corpuscles and obtained a positive reaction in thirty of the forty-five cancer cases, both tests giving positive findings in seventeen of the forty-five patients. In eight of the forty-five cases neither test elicited a positive reaction. It thus proved possible to obtain a positive reaction by one or the other test in 80 per cent. of the forty-five cancer cases, while the reaction was positive in only six of the eighty-five patients with non-malignant affections. [The technic for the meiostagmin test was given in THE JOURNAL, May 28, 1910, page 1790]. Kelling has modified his hemolytic test and commends the later technic, III, as simpler and more reliable. The human serum to be examined is inactivated at 55 C. for half an hour; then 0.5 c.c. is added to 1 c.c. of a 5 per cent. suspension of hen red blood-corpuscles in 0.85 per cent. salt solution. The mixture is set aside for an hour at a temperature of 37 C. and then is rapidly rinsed twice with physiologic salt solution and centrifugated. To the sediment is then added physiologic salt solution to 1.5 c.c. and the whole is well shaken, after which 0.05 c.c. of normal active human serum is then added. The test tubes are then incubated until the control tubes with the inactivated normal serum turn pink. The tubes are then shaken up, centrifugated and titrated. The results are listed according to the percentage of normal hemoglobin, for example, 60 represents 60 per cent. hemoglobin dissolved. He tabulates the parallel findings with the meiostagmin reaction and with the three forms of the hemolytic test as recorded for 130 patients. As the reaction is a biologic one, its failure in 20 per cent. is no more than might be anticipated. A record of 80 per cent. positive reactions with cancer in such a large number of cases confirms the claims of the inventors of the tests as to their specific nature and reliability, while the simplicity of the technics, Kelling adds, places these tests within the reach of all.

123. **Adhesive Plaster Garter in Treatment of Varicose Veins.**—Büdinger winds a few turns of cotton cloth about 10 cm. wide around the leg below the knee. Over this he winds three of four spiral turns of a strip of adhesive plaster about 4 cm. wide, until the plaster forms a band about 6 cm. (nearly 2½ inches) wide. This plaster garter is drawn tight enough to compress the superficial veins but not enough to cause stasis. The constriction is applied of course with the leg elevated and the venous blood stroked back toward the trunk. When the garter works loose enough for the blade of a pair of scissors to be introduced beneath it, it is removed and a new one applied. This is generally necessary about once a week. Varicose ulcers heal rapidly below this garter and it will be found useful, he declares, in all cases in which operative measures are contra-indicated.

124. **Improved Technic for Electrolytic Depilation.**—Weidenfeld saves time by inserting 150 needles in turn and then applying the electric currents all at once.

132 *Hyperfunctioning of Ovaries or Testicles as Cause of Rachitis. S. Stocker.

128. **Improved Technic for Pubiotomy.**—Mayer has found that the injuries of the soft parts with pubiotomy are due to the sudden stretching apart of the sawed halves, thus pulling on the soft parts with such a sudden jerk that lesions result. This can be avoided, he states, by sawing the bones with the patient in the Walcher position, with the pendent legs held close together. Only when the legs are raised to the horizontal position do the bones gape. The danger from the sudden gaping of the bones was exemplified in v. Rosthorn's case in which immediately after the sawing of the bones they separated with such traction on the soft parts that a fulminating fatal hemorrhage resulted. The pendent legs should be drawn into the horizontal position only with extreme caution and very gradually, to spare the soft parts all sudden traction.

130. **Vaginal Cesarean Section for Pulmonary Edema.**—Massini knows of only three cases on record like his own, in which vaginal Cesarean section was done to relieve fulminating edema of the lungs. His patient was a multipara of 38, who had had edema, nausea and tendency to dyspnea at night during the first three months of the pregnancy. Fulminating pulmonary edema developed suddenly at the eighth month, unmodified by the usual measures; the patient lay in coma and pulseless for moments at a time. She began to breathe better immediately after the vaginal Cesarean section; the interval between the onset of the intense edema in the lungs and the termination of the operation was scarcely twenty minutes. As the uterus did not contract, the placenta was removed by hand and the interior of the uterus massaged and improvement was soon evident but the coma did not subside until the next day. The child was cyanotic to an extent Massini had never before beheld; it had suffered not only from the lack of intake of oxygen by the mother but also from the fact that the mother's blood had evidently drained the fetus of all its oxygen. The woman was soon convalescent.

132. **Ovarian Hyperfunctioning as Cause of Rachitis.**—Stocker implanted in a two-weeks' calf the ovaries from a healthy cow that had calved once. In a few weeks the calf developed a picture resembling in every respect that of rachitis, while the control calf under identical conditions otherwise was strong and lively. These findings and experimental research suggest that rachitis is due to excessive functioning of the ovaries or testicles and that treatment on these lines might prove effective. It has certainly displayed efficacy, he says, in the one clinical case in which he has applied it to date. The patient was a girl of 17 with pronounced rachitis and pains in the bones. She was given the milk of a castrated cow and in a few days the pains disappeared and she began to increase in stature.

133 *Meningism E. Cerrano.

January 17, No. 8, pp. 83-90

134 Experimental Syphilitic Keratitis. (Sull' inoculabilita dell' ulcera venerea nella cornea del coniglio.) A. Fontana.

133. **Meningism.**—Cerrano comments on the difficulty in distinguishing between actual meningitis and the vague condition which he calls meningism. Lumbar puncture is the criterion, and he reports a case in which everything seemed to indicate acute meningitis except the negative findings in the spinal fluid. The meningism may be due to infectious or toxic causes, or reflex, hysteric or physical; in his case it was traceable to gastro-intestinal auto-intoxication and the convulsions and contractures ceased as the intestinal tract was cleared out.

137 *Influenzal Pleurisy and Peritonitis. G. Ghedini.
138 Primary Multiple Malignant Lymphomas of the Jejunum. F. Fulci. Commenced in preceding number.

136. **Tetragonus Myelitis.**—Catola's patient was a girl of 17 with both gonorrhea and syphilis; three months after the development of the syphilitic eruption she began to have fever, headache and paresis of the legs, blending into total paraplegia of the ascending type, fatal the fifteenth day. The findings in the spinal cord were those characteristic of acute poliomyelitis but the symptoms had been more those of Landry's paralysis. A tetragonus in pure cultures was obtained from the blood and cerebrospinal fluid, and this germ was evidently responsible, he thinks, for the syndrome observed.

137. **Influenzal Pleurisy and Peritonitis.**—Ghedini summarizes fifty-two articles on this subject which he has found in the literature and reports seven cases from his own experience, one of which has never been reported before. In three of his cases the influenzal bacillus induced pleurisy with effusion, in one pleurisy without effusion, in one peritonitis with effusion and in two others several of the serous membranes were involved with considerable effusion. Treatment, he states, is that for influenza in general, and is based mainly on quinin. *Differentiation is easy if a preceding attack of influenza gives the clue but it may be difficult in the absence of this.* The sudden onset, the intensity of the symptoms, the brief course and the favorable outcome distinguish the influenzal from tuberculous pleurisy and peritonitis, while the benign course and lesser tendency to recur differentiate it from streptococcus and staphylococcus processes. Bacteriologic examination of the effusion or blood or serodiagnosis may be necessary in *some* cases.

142 *Prognosis of Traumatic Neuroses. J. Billström. Commenced in No. 10.

142. **Traumatic Neuroses.**—Billström gives full summaries of 103 cases of traumatic neuroses, including seven from his own experience. The list is based on the records of several clinics and insurance societies in Sweden. Complete recovery sooner or later was the rule in 90 per cent.; the longer the interval the larger the number of complete cures observed. The local and monosymptomatic forms of hysteric or pure neurasthenic traumatic neuroses give the best prognosis. Suggestion from the physician making the examination, and especially repeated examinations, render the prognosis less favorable, he has found, and he warns that the certificate should never be accessible to the patient. The Swedish insurance societies do not regard traumatic neuroses as entitling to an indemnity and this aids in reducing the tendency to exaggeration of the trouble on the part of the injured. *But it is extremely important, Billström emphasizes, to distinguish between the "pure" and the complicated cases of traumatic hysteria.* In case of an indemnity, the prognosis is better when it is paid in a lump sum rather than as a pension. Among his seven cases complete recovery followed after a few months or years—the interval being eight years in one case during which time there had been periods of freedom from the neurosis followed by recurrences under emotional stress. One puzzling case proved to be malingering, the home physician sending in an intentionally misleading certificate. One patient is still unduly nervous but for this his chronic alcohol addiction may be responsible.

PURULENT INFECTIONS OF THE URINARY TRACT IN INFANCY *

JOSEPH BRENNEMANN, M.D.
CHICAGO

Purulent infections of the urinary tract are by no means infrequent in infancy and early childhood. They form probably 1 per cent. of all the illnesses that bring these little patients under the physician's care. Roughly speaking, I should estimate them to be about as frequent in my own practice as meningitis. These infections still occupy rather a unique position, in that they are almost never recognized in general practice. This is not because the babies are not sick, or because the diagnosis is difficult. The babies are alarmingly ill, have long-continued high septic fevers and become emaciated and anemic to an extreme degree, and a considerable per cent. die if untreated. The diagnosis, on the other hand, is easy and positive, and can be made by any one who can recognize a pus cell under the microscope. The reason why the diagnosis is not made in these cases is that it has not yet become generally known that pyelitis, or pyelocystitis, manifests itself, *sui generis*, in infancy as a not infrequent, serious, sharply defined, and easily recognizable disease.

Forty years ago Goschler[1] wrote of these infections in association with vulvitis in new-born infants. Twelve years later Hirschsprung,[2] of Copenhagen, again spoke of them in a paper advocating the free use of diagnostic catheterization in infants. As so frequently happens, but little attention was given to the subject until Escherich[3] in 1894 emphasized it in a paper, in which he reported seven cases—and later on, fifty more—that were nearly all due to the colon bacillus. Holt,[4] Trumpp,[5] Heubner,[6] Finkelstein,[7] and many others, quickly reported further cases that confirmed these findings. In England, Box[8] and especially the great Edinburgh pediatrician, Thompson,[9] have contributed notably to our knowledge of the subject. In this country, Holt,[4] Fischer,[10] Freeman,[11] Morse,[12] Zahorsky,[13] Abt[14] and others have reported many cases and have added materially to the literature. A series of eighty cases from Finkelstein's clinic has just been reported by Friedenwald,[15] twenty-two cases occurring in the last year, at the Kinderasyl.

A most valuable statistical contribution, because it helps us to realize in some measure the extent of this disease, was given by Goeppert.[16] Two years ago he reported 126 cases that occurred in his private practice in the little town of Kattowitz, in Oberschlesien, in a period of eight years, and estimates that in the limited area of which Kattowitz is the center, some eighty cases occur annually. In the last six years more than 1 per cent. of all of the patients that came to his office were thus afflicted. There is no reason for believing that the disease is less frequent elsewhere.

The clinical picture is in its main features a fairly constant one. A female infant becomes suddenly seriously ill with a high temperature, running commonly to 103 or 104 F., not infrequently to 105 and even 106 F. Vomiting, lack of desire for food, restlessness, etc., occur, as in all high fevers. Convulsions may usher in the attack, as one might expect, though probably no more frequently than in other high fevers. Thompson[9] has especially emphasized the recurring chills as a characteristic symptom, finding them in eight out of fifteen cases, while others have not found them so frequently. The rareness of a distinct chill in early childhood makes this a valuable symptom. The respiration is often disproportionately increased and a slight cough is common. There is frequently some indigestion that can easily lead to an improper diagnosis. The child is usually rather excitable, wide awake, restless, the eyes are bright, and the face sometimes wears an anxious expression.

A striking symptom that is of considerable diagnostic value is the extreme pallor that comes after the flushed condition of the first few days. The child is either white, as shown so well in the bloodless paper-like whiteness of the ears, or else it is a grayish, ashy white.

These children are commonly very sensitive to handling, and cry when approached, and especially when made to sit up or when lifted by the shoulders. This is probably due to the fact that there is often distinct tenderness over one or both kidneys. If the trouble is unilateral the child may wince or even cry out when the affected side is palpated. Often there is distinct muscular rigidity anteriorly over the kidney. The kidney itself is rarely palpable, partly because of the muscular rigidity and partly because it is rarely enlarged sufficiently. In cases in which the pelvis becomes distended, owing to temporary obstruction of the outlet, a considerable mass may be made out that may lead to a suspicion of pyonephrosis or even appendiceal abscess. Colicky pains are not uncommon.

The course of the disease if untreated is essentially chronic. The temperature persists as a septic, remittent or even intermittent fever. These cases are often diagnosed as malaria, typhoid, food intoxication, or, if the nervous symptoms are marked, as is frequently the case, as meningitis, and later, when the condition shows no tendency to improvement, as a chronic tuberculosis of uncertain localization. In many cases the disease becomes distinctly intermittent; days, weeks, or even months of normal temperature and general well being, with rapid gain in weight, will separate periods of a week or of several weeks of high fever and all the other symptoms of a fresh acute infection. In one case that occurred early in my practice which I failed to diagnose, I had a favorable opportunity to observe this condition. Four or five distinct relapses or exacerbations occurred during a period of about four months, each lasting from one to three weeks with a general tendency to greater severity, and a more prolonged course in each new attack.

From the clinical course so far, it is evident that these cases do not differ sufficiently from other acute and chronic infections of various kinds so that they can be diagnosed readily from this alone. The positive diagnosis is made when pus is found in the urine. The amount of pus varies much in different cases and in different specimens from the same case. Commonly the urine appears turbid, sometimes even thick and milky. A nearly normal specimen may precede or follow one that is loaded with pus on account of a temporary obstruction of the ureter of the affected side. Microscopically, pus-cells singly and in clusters usually pack the field. Goeppert[16] has suggested an arbitrary minimum diagnostic standard of six to eight leukocytes in each field of an uncentrifuged specimen. Bladder and renal epithelium are present in varying degrees. Albumin is always found if there is enough pus. If it is out of proportion to the amount of pus, it speaks for an involvement of the kidney itself, a pyelonephritis. Casts are not found unless there is a complicating nephritis. The urine is almost invariably acid when first passed always in colon infections, and contains large numbers of long bacilli.

In some cases there is apparently a bacteriuria rather than a pyuria. In these the urine swarms with bacteria; usually colon bacilli and few pus and epithelial cells are found. In some of these, as in ten cases described by Mellin,[17] there were *no* constitutional symptoms, and one can hardly believe that we have here to deal with an inflammatory process, but rather with a simple multiplication of bacteria in a favorable medium. In others, which present constitutional [illegible] pallor, loss of appetite, etc., as in [illegible] there is doubtless a true inflammatory process with but little formation of pus. These cases are rare and little is known about them. I have seen *one* case that apparently came in this catagory. The child seemed clinically to have a severe case of pyelitis; the acid urine showed almost no pus but teemed with bacilli.

Frequent urination and tenesmus seem to occur in only a small proportion of cases and can hardly be accorded much, if any, diagnostic significance. In one case in which Thiemich found a marked cystitis at autopsy, no history of these symptoms was obtainable during life. When we consider furthermore how frequently mothers tell us that their babies "wet every few minutes" or that they cry before, during, or just after urinating, without any demonstrable lesion, it is evident that these symptoms are peculiarly unreliable in an infant.

When we sum up the clinical picture of this disease we are struck by the fact that the great majority of these infants give no single physical sign or symptom that points positively to the kidney or bladder as the site of the trouble, until we examine the urine.

ETIOLOGY

Pyelocystitis is characteristically a female disorder. I have myself never seen it in a male infant. Goeppert,[16] whose statistics are relatively higher than those of others, but whose larger material has especial value, found 10 per cent. of his cases in boys and 90 per cent. in girls. In Finkelstein's[15] series 27 per cent. were males, showing that males are much more commonly affected than was formerly believed, or else, as seems more probable, that the conditions in a foundling home are different from those of private practice.

The great majority of these cases occur during the first year, with especial predilection for the second and third quarters of the first year (Goeppert[16]) or according to Finkelstein's[15] series the first quarter. After the second year they are relatively rare and probably approach the adult type.

This infection takes place more frequently during the summer months. This at once suggests a connection with summer diarrhea, and it is a significant fact, as will be seen later, that many of these cases are preceded by a food disturbance. Social status has less significance than one would expect, and I have been struck with the number of cases that occur in which the babies are under ideal surroundings as to care and cleanliness.

The *Bacillus coli communis* is the direct cause in the great majority of cases, in about 97 per cent. of both Escherich's and Goeppert's series. In the remaining cases one or the other of the common pyogenic bacteria is the cause.

PATHOLOGY

The pathology is still variously interpreted. Escherich[3] in his first paper considered the disease purely a cystitis. Finkelstein[7] and Trumpp[5] both retained this term but in a limited number of cases were able to demonstrate post mortem that the pelvis of the kidney was likewise involved. Heubner[6] first distinguished between a cystitis and a pyelitis and retains this classification in his text-book. Goeppert,[16] who has had apparently very few if any autopsies, chooses to call the disease "pyelocystitis with especial emphasis on the first syllables" and thinks that in most cases the pelvis and bladder are involved, but that the pyelitis is the important lesion in the great majority of cases, and that only exceptionally does a cystitis dominate the picture. Thompson[9] and Still[18] consider the disease a pyelitis. American authors commonly speak of the disease as pyelitis, or pyelocystitis. In twenty autopsies of Finkelstein's series fifteen cases showed involvement of both bladder and pelvis of the kidney; three of the pelvis, and one of the bladder alone.

A most valuable contribution to the subject has just been made by Thiemich[19] of Magdeburg. From a series of autopsies he establishes the fact that in a certain proportion of cases there are found post mortem as the dominating lesion multiple, minute abscesses of the cortex of the kidney, sometimes radiating toward the pelvis as fine lines. He reports three autopsies in boys and three in girls in which this condition was present, and in which the inflammation of the pelvis or bladder was so slight that it was almost unrecognizable. The fact that he has found this condition so frequently post mortem does not establish its relatively frequent occurrence, because it is only in these severer cases that patients die of the disease itself; the others do not come to the post-mortem table. Nearly half of the autopsies reported by Friedenwald[15] in Finkelstein's series belonged to this type, showing miliary abscesses in the cortex, and kidney substances, as well as a catarrhal condition of the pelvis and bladder.

---

[17] Mellin: Quoted by Langstein in Pfaundler and Schlossmann's Handb. der Kinderh., first German edition, 1906, p. 578.

[18] Still: 'Common Disorders and Diseases of Childhood, 1909.

[19] Thiemich: Ueber die eitrigen Erkrankungen der Nieren und Harnwege in Saüglingsalter, Jahrb. f. Kinderh., September, 1910, 72 d. Dritten Folge, xxii, 243.

From a pathologic standpoint there are, then, two types of the disease: 1. The great majority of the cases are catarrhal infections of the bladder and pelvis of the kidney; i. e., pyelocystitis. These are of all degrees of severity but are generally benign and occur almost exclusively among girls. This is the type commonly seen.

2. The severe type that affects children of lowered resistance, due to some infection or food disturbance, in which the cortex of the kidney is studded with miliary abscesses, and in which the involvement of the pelvis or bladder is of less importance; i. e., a pyelonephritis.

The pathogenesis offers an interesting field for speculation. The fact that nine out of ten of these cases, perhaps ten out of ten of the ordinary type of pyelocystitis, occur in females demands an explanation. If we combine this with the further facts that 97 per cent. of these cases are due to the colon bacillus, and that 60 per cent. of Goeppert's cases occurred during the first year, 80 per cent. during the first eighteen months, and 90 per cent. during the first two years, and 92.5 per cent. of Finkelstein's cases during the first year, i. e., during the diaper age, an explanation thrusts itself on us. If one bears in mind the extreme shortness of the infantile female urethra, and then sees such a little girl "changed" after she has had a very soft or liquid bowel movement that floods the vulva and is pressed against the urethral outlet, there is little difficulty in believing that colon bacilli are carried through the urethra to the bladder and there set up an inflammation that in turn is carried to the pelvis of the kidney. The frequent association of this disease with diarrhea adds to the plausibility of this view.

While an ascending infection of such an origin has seemed the most reasonable explanation of pyelocystitis, there can be little doubt that the cases of pyelonephritis described by Thiemich[19] and Friedenwald,[15] with cortical abscesses as well as catarrhal involvement, are of hematogenous origin. Whether this mode of origin plays any considerable part in the former type remains to be determined. It would be very instructive to know whether the colon bacillus is as frequent, relatively, in the cases of pyelonephritis as in those of pyelocystitis. A third possible source of infection has been suggested—that of direct migration of the colon bacillus from the intestinal to the bladder wall.

DIAGNOSIS

The diagnosis of pyelocystitis is made when a sufficient amount of pus is found in the urine, at least six to eight leukocytes, to the field of a non-centrifuged specimen. One must always remember that a single specimen may be nearly normal, and in every suspected case repeated examination should be made. The possibility of contamination with vaginal discharge or with feces must be guarded against in an infant. An exact anatomic diagnosis can hardly be made, since ureteral catheterization is not feasible. The milder cases may be a simple cystitis; the severer cases, with high fever and serious constitutional symptoms, are probably nearly all cases of pyelitis or pyelocystitis; the rarer severe cases which complicate other conditions, which do not yield to treatment, and in which a larger amount of albumin is found in the urine than one would expect from the amount of pus, probably belong to the type of pyelonephritis. An examination of the pus and epithelial cells gives but little if any practical assistance in an accurate anatomic diagnosis.

The greater difficulty in procuring a specimen of urine in an infant is one reason why urinalysis is more often neglected than in the adult. And yet this difficulty can always be overcome and is no excuse for a failure to examine the urine. Specific directions must be given to insure success. In the male child a rubber finger cot or condom can be left in place until the child urinates. In both sexes, in older infants, if the child is quickly placed on a chamber, after a long nap it will usually urinate. If this is not successful, the infant can be washed clean and left until it urinates on a clean rubber sheet or oil-cloth, so arranged that the lowest part is in the region of the buttocks. If there is a diarrhea, or if this method cannot be employed for some other reason, then the mother or nurse can watch the exposed baby, cup in hand, until the moment arrives when the urine can be caught. This may be tedious, but it is important. Finally, if these methods fail, or if one wants an uncontaminated specimen for bacteriologic examination, the catheter with proper aseptic precautions can be freely used, as urged by Hirschsprung[2] thirty years ago. The use of a mass of cotton cannot be recommended, as it is apt to sift out many of the pus-cells, and is otherwise not as serviceable as the other methods.

While a urinalysis is imperative for a positive diagnosis, in many cases after a little experience a fairly certain diagnosis can be made without it. A persistent high temperature in a female infant, sensitiveness, a striking ashy pallor, the occurrence of chills, with practically no physical findings to point to any localization, indicate with a great deal of probability a pyelocystitis. The utter disproportion between the severity of the disease and the physical findings is strongly diagnostic.

PROGNOSIS

In the ordinary type, that of pyelitis or pyelocystitis, which forms the great bulk of these cases, the prognosis is distinctly favorable. In some fifteen cases that I have seen no patient has died.[20]. In Goeppert's[16] cases, on the other hand, the mortality was 12 per cent., or, if one includes three cases in which the urinary infection was only partially the cause of death, and three others that left treatment in a critical condition, the mortality was even 20 per cent. Such a mortality requires qualification. The prognosis of these cases depends materially on the treatment. If the patients are untreated, the prognosis is bad; if they are properly treated, it is very good. Goeppert's cases were practically all among private office patients, the majority of these among the poorer classes, among whom a rigid, persistent treatment was impossible. His mortality statistics cannot therefore be applied to more favorable conditions.

---

[20] Since writing this I have had a fatal termination in an infant of 3 months.

Friedenwald[15] speaks of twenty autopsies in Finkelstein's series of eighty cases, a mortality of 25 per cent. From the nature of the material probably only a proportion of the patients died of the disease itself. Deductions from the morbidity of a foundling asylum would not apply to private practice. The pyelonephritis cases offer a more gloomy prognosis, partly because of the seriousness of the lesion, partly because of the previous weakened condition of the child. These cases are not hopeless, however, since there is a natural tendency to arrest, resorption, and cicatrization of the little abscesses, and very little tendency to the formation of large abscesses that would require surgical treatment. It is hard to believe that these cases occur in any considerable number, and in general one is justified in saying that the prognosis of the urinary infections in early childhood is distinctly good as to life and cure, though many of them drag along for months.

TREATMENT

There is little that can be offered in the way of prophylaxis, except local cleanliness, the avoiding of diarrheas and infections and the maintaining of the general health at a high level.

After the disease is established the child should be kept quiet, its diet should be watched carefully, and it should be given an abundance of liquids, especially water or alkaline waters, to flush the urinary tract.

The English writers, especially Thompson[9] and Still,[18] give large doses of alkalies, especially potassium citrate, half a dram to a dram or more a day in divided doses. Thompson's[9] statement is well worth quoting:

> The main and the only essential treatment consists in rendering the urine neutral, when passed, by the administration of alkaline remedies, as speedily as possible, and in keeping it so until all the symptoms have disappeared. When this indication is thoroughly carried out, its good results are very remarkable. The pain and uneasiness rapidly vanish and the temperature falls to normal within three days. The pus cells also disappear. The bacteria, however, may persist for a long time after the pus has gone; but they seem to do no harm. . . . The alkaline treatment must be continued for a week or two at least, in spite of the depressing effect which it has on the child's general condition and the loss of appetite which it is apt to occasion. If it is stopped too soon the symptoms return.

Nearly all German and American clinicians depend on urinary antiseptics, hexamethylenamin (urotropin) and phenyl salicylate (salol), as of first value, and recommend alkaline drinks as of value in diluting and possibly alkalinizing the urine. Heubner[6] warmly recommends hexamethylenamin in doses of 1 to 2 grains three times a day. Finkelstein prefers salol. Goeppert uses salol in all acute cases, in doses of 1 to 3 grains five to eight times a day for ages varying from two months to two years, and finds, "as early as thirty hours after its administration a decided improvement in the general condition." After the acute stage he uses hexamethylenamin and throughout urges the ingestion of large amounts of water, especially alkaline waters, even giving it by gavage and enema if not well taken by mouth. He expects a cessation of fever and of discomfort in the first two or three weeks and a pus-free urine in five weeks, and maintains that many cases get well in five to eight days.

Such rapid improvement has not been the rule in my own experience. Many of the cases drag along for months, often with distinct intermissions, in spite of any treatment. Ultimately the patients are cured clinically, in nearly all cases. My own procedure is to crowd water in every way, to try alkalies first, and if there is not a decided improvement in a few days, to substitute hexamethylenamin, or salol in doses of 1 to 2 grains every three or four hours to an infant 1 year old and to keep this up for a long time to avoid the relapses that are only too common.

The severer cases with cortical abscesses, of course, are influenced but little by any of these remedies. They require also treatment of the underlying condition and general tonic and supportive measures.

In conclusion, permit me to emphasize the one important point in the subject that I have discussed: In every child, and especially in every female infant, that has a continuous or intermittent high temperature, the cause of which is not clinically obvious, an examination of the urine for pus is imperative.

THE ESOPHAGOSCOPE IN REMOVING SHARP FOREIGN BODIES FROM THE ESOPHAGUS

WILLIAM LERCHE, M.D.
ST. PAUL, MINN.

The impaction of sharp foreign bodies in the esophagus is of comparatively frequent occurrence, but the rational treatment thereof—the extraction by esophagoscopy—has apparently not received the attention that it deserves.

The esophagus at times seems remarkably tolerant to the presence of foreign bodies; in some instances such bodies have remained in the organ for years. On the other hand, cases are on record in which death has followed in twenty-four hours after the accident.

Any foreign body lodged in the esophagus should be promptly removed, but I wish particularly to call attention to the danger of procrastination when we have a sharp foreign body to deal with.

It has been my fortune to relieve a number of patients who have accidentally had foreign bodies impacted in the esophagus. Those which I have extracted have been of various kinds, but pieces of bone have impressed me as being particularly dangerous.

SYMPTOMS AND TREATMENT

Pain and difficulty in deglutition and tenderness of the neck, with rise in temperature, are the main symptoms of a sharp foreign body in the cervical part of the esophagus. If a perforation of the esophageal wall has taken place in the cervical part there will be an emphysematous condition of the neck. When the foreign body has become impacted in the thoracic part of the esophagus there may be pain and difficulty in deglutition, but it must be kept in mind that there may be no symptoms whatever until perforation takes place.

As the first step in treatment, the pharynx, the pyriform sinus and the inlet of the esophagus is anesthetized with a 10 per cent. solution of cocain, and the esophagoscope, without the obturator, is introduced under the guidance of the eye. When the foreign body comes into view its position is noted, and with a special forceps it is carefully dislodged and extracted. Esophagoscopy generally ought to be done without the aid of an obturator, in order to enable the operator to inspect the entire tract through which the instrument passes, but that is a matter of choice. In case of sharp foreign bodies, however, the obturator must never be used, because damage may be done to the wall of the esophagus by pushing on the sharp foreign body. For the same reason the bougie, the probang, and similar instruments must be condemned. It will readily be seen that additional injury might be done in a case like my Case 2, reported below, the actual condition of which is pictured in Figure 6, if an instrument is introduced blindly. The use of a sound or bougie for diagnostic purposes may be deceiving, as these instruments, in several instances, have failed to demonstrate the presence of even a large foreign body. The forceps used for the extraction of foreign bodies belongs to a set of instruments, which I have devised for esophagoscopic and bronchoscopic work.[1] When the foreign body has been caught in the forceps the instrument can be locked.

Fig. 1.—Piece of mutton-bone (actual size) removed from patient's throat (Case 1).

Fig. 2.—Beef-bone (actual size) removed from patient's throat (Case 2).

It may be necessary to cut or break the foreign body before it can be extracted, and for that purpose Kahler's forceps is useful. Thus a tooth-plate impacted in the esophagus can be reduced in size by cutting with Kahler's forceps, or it can be burnt through by a specially made galvanocautery point or snare.

The accidental swallowing of an open safety-pin is not infrequent. The pin enters the esophagus with the point upward, and traction on the pin in the latter direction would naturally force the point into the esophageal wall. For the purpose of closing the open safety-pin *in situ* and extracting it through the esophagoscope I have devised an instrument shown in Figure 7. The instrument is introduced with the wire loop C withdrawn. When the latter is below the safety-pin the wire loop is pushed out by pressing the lever on the handle and pulled up on the open pin. The steel wire B with the hook D on the distal end is now pushed down and turned on to the pin, after which the loop is closed, locking the pin. The steel wire with the hook prevents the safety-pin from slipping up when the loop closes in on it.

If the foreign body has perforated the wall of the esophagus and caused a periesophageal abscess in the cervical part, the use of the esophagoscope is contraindicated. Such an abscess must be dealt with from without, and as early as possible in order to prevent the burrowing of pus into the posterior mediastinum. If the foreign body has perforated the thoracic part of the esophagus and caused a mediastinal abscess, the use of the esophagoscope is imperative before opening the mediastinum in order to determine on which side the abscess is located. A case illustrating this point is reported in recent German literature, in which the posterior mediastinum was entered without finding the abscess. Post mortem the abscess was found to be in the mediastinum on the opposite side. It was shown that this could have been determined by esophagoscopic examination before the operation.

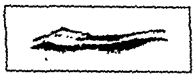

Fig. 3.—Fish-bone (actual size) removed from patient's throat (Case 3).

Fig. 4.—Fish-bone (actual size) removed from patient's throat (Case 4).

To perform esophagotomy in case of impacted foreign body, before extraction by the esophagoscope has been tried, is not justifiable for the reason that esophagotomy for the removal of foreign bodies has considerable mortality. In 326 cases of external cervical esophagotomy for the removal of foreign bodies collected by Balacescu and Kohn,[2] the mortality was as follows:

In the pre-antiseptic era (prior to 1880)	26.5 per cent.
In the transitional stage (1880-1890)	27.8 per cent.
In the antiseptic era (1890-1900)	17.8 per cent.
In the aseptic era (1900-1903)	12.6 per cent.

Nauman[3] has later collected forty additional cases with a mortality of 17.5 per cent.

REPORT OF AUTHOR'S CASES

Case 1.—Mrs. F. T., aged 45, had swallowed a piece of mutton-bone which lodged in the throat forty-eight hours previous to consultation. Swallowing had been very painful since. Esophagotomy had been advised before the patient was referred to me. The neck was very tender on palpation, especially on the left side. No emphysema of the neck. Temperature was 102 F. After cocainizing the throat the esophagoscope was introduced and the bone found in a slanting position in the middle of the cervical part of the esophagus, the lower end being embedded in the mucosa. The bone was grasped by the forceps and quickly extracted. It was 2 cm. in length and very sharp at both ends (Fig. 1). Recovery ensued.

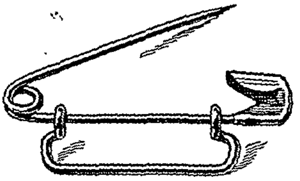

Fig. 5.—Safety-pin (actual size) removed from patient's throat (Case 5).

Case 2.—Mrs. L. A., aged 58, while taking her evening meal three days previously to consultation, had swallowed a piece of beef-bone, which stuck in her throat. The neck was very tender to touch, more so on the right side, and the patient suffered great pain on swallowing. There was no emphysema of the neck. The temperature was 103 F. Through the esophagoscope the bone was seen crossways in the lower cervical part of the esophagus, with both ends buried in the wall (Fig. 6). When it was extracted foul-smelling pus welled up from the right wall. The piece of bone measured 18 mm. in length, was rough and sharp at both ends (Fig. 2). Pus discharged through the mouth for some time. On esophagoscopic examination a few weeks later the abscess cavity, which evidently had been in the submucosa, had closed. Recovery ensued.

Case 3.—A. J., aged 65, had had a fish-bone lodged in his throat eight hours previous to consultation. Some blood came up shortly after the accident. Deglutition was painful. No emphysema of the neck existed. Esophagoscopic inspection disclosed the fish-bone in the lower cervical part of the esophagus. It was removed by forceps. The lower end of the bone was engaged in the mucosa. It was quite stout, sharp, and 16 mm. long (Fig. 3). Recovery occurred.

Case 4.—C. D., aged 25. A fish-bone lodged in the patient's throat seven hours previous to consultation. Deglutition was quite painful. There was no emphysema of the neck. Esophagoscopy revealed a bent fish-bone, with the convexity upward, in the cervical part of the esophagus. The bone was easily extracted (Fig. 4). Recovery.

---

[1] Illustrations of these instruments appeared in my article, Contribution to the Surgery of the Esophagus, Surg., Gynec. and Obst., October, 1910.

[3] Nauman: Deutsch. Ztschr. f. Chir., 1906, lxxxiii, 479.

Case 5.—A girl, aged 2, swallowed an open garter safety-pin four hours previous to consultation. The child was crying constantly. Respiration was normal. The esophagoscope was introduced without the administration of an anesthetic, and the lock end of the pin was seen at the inlet to the esophagus with the point imbedded in the anterior wall. The point was dislodged and the pin extracted (Fig. 5). Recovery.

In the first four of these cases the foreign bodies were removed quite readily. Case 5, on the other hand, was very difficult, because the safety-pin was a large one with a strong spring; furthermore, the point was well engaged in the wall and the garter-buckle increased the difficulty to a considerable degree.

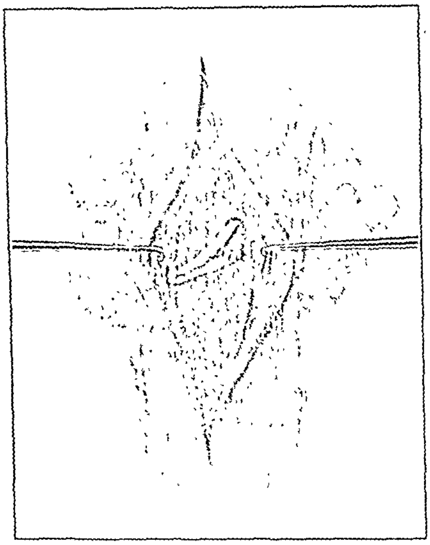

Fig. 6.—Piece of beef-bone, 18 mm. in length (shown in Fig. 2), lodged in patient's throat (Case 2).

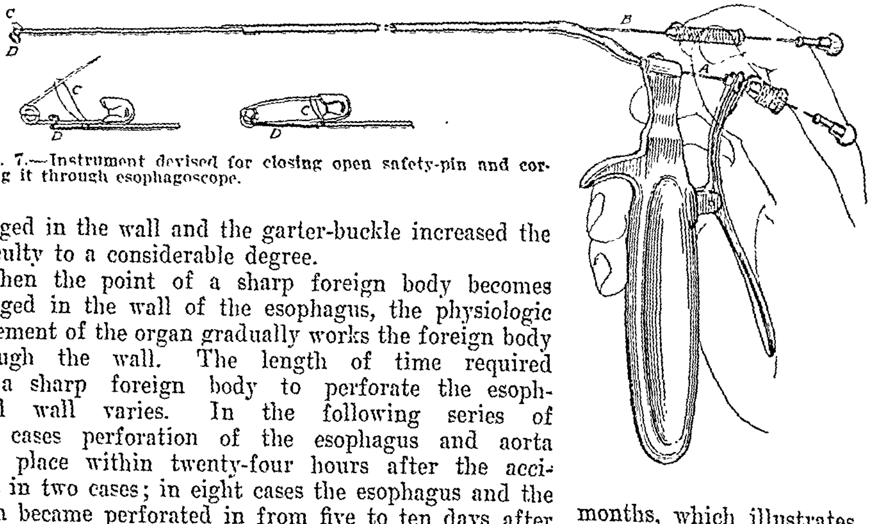

Fig. 7.—Instrument devised for closing open safety-pin and correcting it through esophagoscope.

When the point of a sharp foreign body becomes engaged in the wall of the esophagus, the physiologic movement of the organ gradually works the foreign body through the wall. The length of time required for a sharp foreign body to perforate the esophageal wall varies. In the following series of 200 cases perforation of the esophagus and aorta took place within twenty-four hours after the accident in two cases; in eight cases the esophagus and the aorta became perforated in from five to ten days after the accident. There have been no deaths among the patients whom I have treated.

CASES FROM THE LITERATURE

In order to ascertain the fate of swallowed foreign bodies in a larger number of cases, I have collected reports of 200 cases from literature since the year 1900. In these my own cases are not included.

The mortality in the 200 cases was 12.5 per cent (twenty-five deaths), of which twenty-three deaths, or 11.5 per cent, were due to perforation of the esophagus with its consequences.

The seat of perforation was:

Upper thoracic part in	15 cases
Cervical part in	5 cases
Lower thoracic part in	1 case
Location not mentioned in	2 cases

(The aorta was perforated in twelve cases, and the common carotid artery in one case.)

The foreign bodies causing perforation and death were:

Piece of bone in	10 cases
Pins and needles in	4 cases
Coin in	3 cases
Fish-bone in	2 cases
Tooth-plate in	2 cases
Iron-washer in	1 case
Brooch in	1 case

Splinters of bone caused the highest mortality in the cases collected by me, and in the series of Balacescu and Kohn, above referred to, twenty-two patients out of seventy-nine who had splinters of bone impacted, died after esophagotomy.

There were no deaths in the forty-seven cases in which the foreign body was removed by esophagoscopy except one, in which previous attempts had been made to extract the bone with the coin-catcher. These attempts had caused a long rent in the wall of the esophagus followed by mediastinitis and death.

There were forty-one different kinds of foreign bodies, of which the following were the most frequent:

Tooth-plate in	41 cases
Piece of bone in	34 cases
Coin in	26 cases
Pins and needles (common pins, scarf-pins, hat-pins, darning-needles, etc.)	22 cases
Open safety-pin in	18 cases
Fish-bone in	4 cases
Metal whistle in	7 cases
Metal button in	5 cases
Piece of wood in	4 cases

The location of the foreign body in the esophagus was mentioned in 118 cases as follows:

Cervical part in	58 cases
Upper thoracic part in	33 cases
Lower thoracic part in	27 cases

Tooth-plates were the most frequent foreign body impacted in these series. Nine tooth-plates were passed per rectum, thirteen were removed by esophagotomy, eleven by esophagoscopy, five by gastrotomy, etc.

In several of these cases the plate had remained in the esophagus for many months, which illustrates what a remarkable tolerance the organ occasionally will exhibit. In one case a tooth-plate remained above the cardia for several months without symptoms, then distress and pain occurred. Death followed operation. In another case the plate remained in the esophagus for eighteen months before it perforated the bronchus; after operation, death occurred. Another patient was relieved of an impacted tooth-plate eleven months after by combined gastrotomy and esophagotomy. One case is reported in which a tooth-plate remained in the upper thoracic part of the esophagus for four months, causing a perforation into the trachea. The plate was then extracted and gastrostomy performed.

The tracheo-esophageal fistula subsequently healed. Recovery.

The methods of treatment used in these cases collected by me were:

Esophagoscopy in	47 cases
Esophagotomy in	27 cases
Gastrotomy in	10 cases
Esophagotomy and gastrotomy in	2 cases
Esophagotomy and esophagoscopy in	1 case
Coin catcher in	12 cases
Probang in	5 cases

The longest time a foreign body remained in the esophagus before being successfully extracted was four years. In one case a coin remained four and one-half years in the esophagus; then it caused perforation and death.

The youngest patient on whom esophagoscopy was performed was 4 days old (extraction of a rubber nipple). The oldest patient on whom I personally have performed esophagoscopy was 86 years old.

Besides the twenty-three cases of perforation of the esophagus in these series, there were eighteen cases of perforation of the abdominal or pelvic viscera, with two deaths.

CONCLUSIONS

1. Esophagoscopy is not a difficult procedure, and it gives the best results in the treatment in these cases, with the least discomfort to the patient.
2. The use of instruments in the esophagus, except through the esophagoscope, in case of sharp foreign body, should be abandoned.
3. In every case in which the swallowed foreign body is not recovered, an esophagoscopic examination of the esophagus should be made.
4. Even if the foreign body is successfully pushed into the stomach, the patient is not entirely beyond danger.

GRAVES' DISEASE

A NEW PRINCIPLE OF OPERATING BASED ON A STUDY OF 352 OPERATIONS *

G. W. CRILE, M.D.
CLEVELAND

Among 219 operations for colloid goiter and benign tumors I had two deaths, one from suppression of urine, the other from myocarditis after healing had occurred. I shall not allude to the malignant and infection cases. My study is of 121 operative cases of exophthalmic goiter, particularly an inquiry into the cause of operative hyperthyroidism, and into the development of a safer technic.

CHANGES IN THE BRAIN CELLS IN A CASE OF GRAVES' DISEASE

In a case of Graves' disease, the patient being unoperated on and free from infection, which ran a natural course to its termination in death, a pathologic examination of the brain and cord was made by Dr. J. B. Austin. The following is his summary:

> In the cord but slight changes were seen; in the medulla there was considerable chromatolysis, the Nissl granules were in moderately fine division, and the nucleus plasma relation was changed; in the cerebellum approximately 30 per cent. of the Purkinje cells were seriously altered and many were destroyed; in the cortex there was marked chromatolysis, the nucleus plasma relation was disturbed and many cells were destroyed. A detailed report will be made elsewhere.

THE CAUSE OF THE SPECIFIC REACTION—HYPERTHYROIDISM—FOLLOWING OPERATION FOR GRAVES' DISEASE

In operations in exophthalmic goiter, the principal risk is an acute exacerbation of the disease, usually called hyperthyroidism, the most conspicuous symptoms being tachycardia, high fever, restlessness, tremor, and finally delirium. Against this risk there is at present no known specific remedy. Were it not for this uncontrollable outburst, the operative risk would be but slight. Surgeons agree that there is a group of cases so severe that an adequate operation cannot by any method be performed safely. It is the purpose of this paper to present a new principle of operating whereby this group of cases may, I hope, be reclaimed. If we are to operate safely we must change our method. To this end we shall first inquire into the cause of the acute hyperthyroidism produced by the operation itself. Resolving the operation into its principal component parts, we have the rôle played by (1) hemorrhage; (2) infection; (3) manipulating and cutting the thyroid; (4) the anesthetic; (5) the psychic disturbances; and (6) the operative trauma to tissue other than that of the thyroid, as factors in the consideration of hyperthyroidism.

HEMORRHAGE AND INFECTION

I have seen acute outbursts of Graves' exacerbation follow a bloodless technic in lobectomy and in simple ligation. Hemorrhage is not, then, an adequate cause.

Infection almost never occurs; Graves' exacerbation frequently occurs. Infection may be excluded.

ABSORPTION OF THYROID SECRETION FROM HANDLING OR CUTTING THE THYROID TISSUE

Patients with exophthalmic goiter are abnormally susceptible to thyroid extract. Serious exacerbation and death have followed a single therapeutic dose of the extract. May there not be an increased absorption of thyroid secretion produced by cutting or handling the thyroid? If so, the secretion must be liberated either by manipulation of the gland or by its discharge from the cut surface. In a serious case I have known the patient to be repeatedly and thoroughly massaged by an osteopath without producing a marked increase in the symptoms. I have never observed an exacerbation follow the physical examination of the gland. In the first instance—the massage—at least, there was certainly more mechanical disturbance than was caused by the very gentle manipulation of the gland in the ligation of a single superior thyroid artery in one emaciated patient, when there followed a fatal outburst of hyperthyroidism. Moreover, Kocher, the creator of the surgery of the thyroid, as a routine measure crushes with a heavy forceps a zone of the gland prior to its ligation and division. He notes no increased hyperthyroidism resulting. In several excisions, in which other factors were excluded and in which there was a certain amount of handling, but trifling reaction followed. At least gentle handling must therefore be but a minor factor.

Is there an increased discharge and absorption of the thyroid secretion from the cut surface of the gland? I

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-First Annual Session, at St. Louis, June, 1910.

have seen no diminution of reaction when the cut surface was immediately treated with pure phenol and alcohol; when immediately seared over with the actual cautery; when the division was made between ligatures; and when the wound was left open and the raw surface was covered with a large gauze pack. On the other hand, I have seen the usual reaction when there was no raw surface left in any part of the wound; and finally I have seen no more reaction when the presumably preventive measures were all omitted. It would appear, then, that the "raw surface" and "squeezed juice" hypothesis do not adequately explain operative hyperthyroidism.

THE ANESTHETIC

Kocher and his school operate under local anesthesia, believing that despite the ordeal there is less reaction following. Mayo and many other Americans use general anesthesia. At first glance it might seem that one or the other method should be the better and should be the method of choice. It can be shown later, I believe, that each has its own field, and that neither can supplant the other.

In several desperate cases, in which the margin of safety of the patients was tested by anesthetizing, without the patients' knowledge, with ether or with nitrous oxid, there was a moderate though short exacerbation of Graves' symptoms following both modes of anesthesia, though more marked in the case of ether. In all cases there is, during the transit from primary to surgical anesthesia, a stage of unpreventable subconscious excitement during which the heart-beat is quickened, respiration is accelerated and in which muscular disturbances may occur. Test doses of morphin and scopolamin, though in certain respects unfavorable, have produced no corresponding exacerbation of symptoms. In severe cases, on the other hand, ligation of the upper poles under local anesthesia, with exclusion of the psychic factor, caused no appreciable reaction. Hence I conclude that general anesthesia, *per se,* contributes a minor factor, and local anesthesia, *per se,* no factor in the production of the specific reaction in Graves' disease.

PSYCHIC FACTOR

Fear may temporarily paralyze normal animals and men. Even death has been caused by fear. It occurred to me that the brain-cells of an animal in intense fear might show physical changes. Accordingly Dr. J. B. Austin and Dr. H. G. Sloan made such observations for me on frightened rabbits. A study of the central nervous system showed the following:

> The cells of the brains that were secured in the midst of fright showed marked hyperchromatism; those that were taken several hours later showed marked chromatolysis, a disturbance of the nucleus plasma relation, and some broken-down cells. The spinal cord showed but slight changes, the medulla more and the cerebellum and cerebral cortex most. These experiments will be elsewhere reported in detail.

The potent influence of the psychic factor in exophthalmic goiter is admitted. This factor alone has caused death in serious cases under both medical and surgical auspices. However, if the surgeon has permission to use his discretion as to the fact as well as to the time of operation, the dangerous psychic factor may be eliminated. The employment of the technic, which will be elsewhere described, by which the exclusion of the psychic factor is effected, enables the surgeon to operate with less reaction in the "fair risks" and to undertake successfully more serious risks, but serious reactions are often seen despite the total exclusion of the psychic factor.

Recapitulating, then, it may be stated that the specific reaction or hyperthyroidism following operation is not due to hemorrhage, to infection, or to an excessive absorption of thyroid secretion from cutting or at least gentle handling of the gland; that it is somewhat influenced by the general anesthetic and markedly influenced by the psychic factor. There still remains the occurrence of specific Graves reaction not accounted for by the factors thus far considered. The only other factor left is the operative trauma of the tissue of the thyroid, and all other tissue as well.

Is the reaction in Graves' disease in cases of trauma of other parts of the body different from that of the normal organism? Barton Cooke Hirst collected and studied reports of 71 operations on various parts of the body other than the thyroid gland in patients suffering from Graves' disease. Many were minor operations, and on the whole the operative risk, had the patients not had Graves' disease, could not have been over 1 per cent. The mortality rate was over 15 per cent. The cause of death in every instance was hyperthyroidism. This table shows that the surgical risk in Graves' disease is as great in operations on other parts of the body as on the thyroid itself, and that the cause of the so-called hyperthyroidism must be found outside of the thyroid gland. My personal cases show a remarkable reaction to trauma. In one patient—a seriously sick one, it is true—a simple hypodermic injection of salt solution, given as a test, caused a psychic storm attended by a leap of the pulse from 140 to 186, with acute cardiac dilatation, trembling, sobbing, rise in temperature, almost overwhelming the patient and lasting over four hours. This is typical though extreme. An analysis of the phenomena will disclose the remarkable fact that the reaction from the mere prick of a sharp needle was perhaps greater than that following a hysterectomy or an amputation in the normal individual, perhaps a thousandfold greater reaction than normal. This is another way of saying that patients with exophthalmic goiter are hypersensitive to trauma just as they are hypersensitive to fear; and fear and trauma are phylogenetically close akin. Possibly this is the master key to our problem.

Arguing from the foregoing hypothesis, I then devised a technic for simple ligation and for excision. A careful inventory is first made of the pathologic physiology of each case. This usually requires several days. During this time a concerted effort is made by nurses and staff to instil hope and confidence into the patient. After such study of the case the type of operation—simple ligation or excision—is decided on.

If excision is to be the procedure the following routine is approximately followed:

> The patient's reaction to small doses of morphin and scopolamin is ascertained. Daily inhalations, which are presumably for some medicinal purpose, but which are precise rehearsals of ether anesthesia, are practiced by the anesthetist, Miss Hodgins. Ether is tentatively dropped on the inhaler along with the volatile oils, and the patient is cautiously, without her knowledge, tried out as to ether anesthesia—sometimes is completely anesthetized—all this in her own bed. The results are then studied and if the patient seems unsuited for the operation of excision, ligation is done as later described. If the central nervous system and heart take the practice march well, the entire operation is then performed as follows: Long previous consent to an operation having been obtained, the patient is given morphin and scopolamin on the appointed morning, is kept absolutely quiet, is then gently

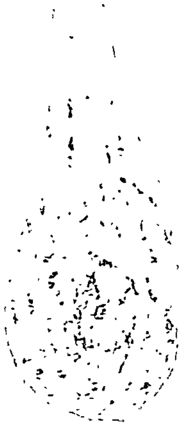

Fig. 1.—Experiment 87. From a case of exophthalmic goiter. The cell has lost almost all its chromatin. The nuclear membrane is ruptured and the nucleolus is breaking down.

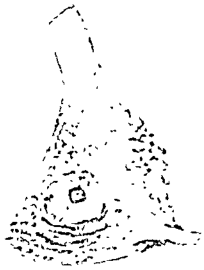

Fig. 3.—Experiment 87. Pyramidal cell from the motor cortex in a case of exophthalmic goiter. Marked loss of chromatin; ruptured nuclear membrane, and a nucleolus which is beginning to break down.

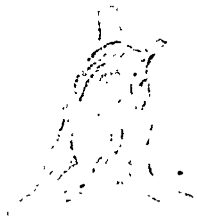

Fig. 4.—Experiment 87. From a case of exophthalmic goiter. Pyramidal cells from the motor cortex. A completely exhausted cell; no chromatin present. The nucleus and the nucleolus have entirely broken down and disappeared.

Illustrating Article on Goiter by Dr. G. W. Crile, Cleveland, O.

anesthetized to the second stage, in bed as before, and is at once taken to the operating-room, where nitrous oxid is substituted for ether. The operative field is as completely cocainized as if no general anesthesia were being given. First the skin and fascia of the opposite side, are incised about one inch. Through this incision, by means of a full curved needle, the upper pole of the gland (Stamm) and all of the overlying tissue inclusive are firmly ligated. Then in the gentlest possible manner the opposite lobe is excised bloodlessly, absolutely avoiding traction on any uncocainized sensitive tissue—precisely as if the patient were awake. After the operation the utmost care is exercised to keep down to a minimum psychic and painful stimuli.

If simple ligation is to be done quite another technic is followed, namely:

After the patient is easy and comfortable under morphin and scopolamin, and not before, I tell her all that she will probably experience. Everything being in readiness—skin, fascia, and muscles—a transverse distance of an inch overlying the upper poles of each thyroid is carefully cocainized. An incision is then made through the skin and fascia, a full curved needle is swept from without inward in such a manner as to include the upper pole of the thyroid, as well as all other structures lying between the bottom of the incision and the larynx. This ligature is then tied and a superficial stitch or two closes the skin. A similar procedure repeated on the opposite side completes the double ligation. It is helpful to chat with the patient meanwhile. The operation is performed on the patient in bed.

The twelve operations performed on this principle are in a class by themselves as to the operative reaction. Even in a case in which the patient's entire body was edematous and the terminal stage of the disease had been reached, the reaction was slight. The technic as a whole is difficult to carry out perfectly. In the strict surgical sense every case by this method is operable at least to the extent of a ligation, though the lesion of the heart and brain may be so extensive as to preclude a final cure.

Granted we have mastered the operation, have we thereby mastered the disease itself? The disease, I believe, may be cured in one or more ways: (1) if the brain cells are sufficiently repaired by absolute rest; (2) if the nerve connection between the brain and the thyroid be interrupted in part by tying the upper thyroid poles, which include half or more of the nerve supply; or (3) if the secreting structure of the thyroid be diminished by partial excision or by cytolytic serum (Beebe's).

Of these three methods excision is the most effective. The immediate relief to the patient following excision is one of the most striking clinical phenomena in surgery.

I therefore conclude that in exophthalmic goiter a pathologic reciprocal interaction between the brain and the thyroid gland exists, and that this reciprocal interaction can be maintained through a nerve connection only. How else could a psychic or a traumatic impulse reach the thyroid and influence its secretion than through a nerve connection or possibly by a hormone action? Many glands of the body respond to adequate psychic and mechanical stimuli. A familiar example is the salivary gland, whose secretion may be excited by the thought of palatable food (psychic), or by the presence of a neutral foreign body—a piece of wood, a pebble, or dental instrument (mechanical). It is generally believed, as opposed to the preceding statement, that the benefit following ligation of the superior thyroid artery is due to the diminution of the blood-supply. In Graves' disease the thyroid, like the placenta in an abdominal pregnancy, builds up a great mass of blood-vessels from the neighboring tissue, especially from the trachea and larynx, so that the superior thyroid not only constitutes a minor part of the blood-supply, but the rich anastomosis revascularizes, probably within a few days, the anemic zone produced by ligation. Then, too, how slightly, as observed in the course of operation, is the hemorrhage diminished by ligation of the superior thyroid artery alone? Simple ligation of the superior thyroid, as it seems to me, is an inadequate explanation of the vast clinical transformation, sometimes lasting months, or even years, following ligation, especially when we take into account the fact that much of the nerve-supply to the thyroid gland enters along the walls of the blood-vessels, and that in ligating the vessels the nerve-supply must be included. May it not well be that the entire mechanism—the cause, the exacerbation and hence the cure—will prove to have a nervous setting and that the thyroid hypersecretion is no more the cause of the disease than is saliva the cause of the psychic phenomena attending the thought of food? Whatever may be the explanation, I draw no conclusion at present.

SUMMARY

The principal points presented in this paper may be summarized as follows:

In one fatal case of simple exophthalmic goiter the brain-cells were found to be widely and extensively affected. Pure fear caused physical lesions in the cells of the rabbit's brain. The principal cause of so-called hyperthyroidism incident to operations on cases of Graves' disease is the adequate psychic and traumatic stimuli, both of which are phylogenetically closely akin; the psychic stimuli may be excluded by special orienting and the traumatic stimuli by an absolute cocainization of the operative field. By a combination of both local and general anesthesia, ligation and excision may be safely done. The value of ligation probably lies mainly in its breaking part of the nerve connection with the brain. The value of excision is the diminution of the total quantity of the gland secreting structure and the breaking of the nerve supply as well.

Between the brain and the thyroid gland in Graves' disease a pathologic reciprocal interaction seems to exist. Patients in Graves' disease are specifically hypersensitive to trauma, to psychic stimuli and to thyroid secretion. When operated on and then immediately returned to the environment that originally produced the disease they frequently relapse. Patients operated on and then given a prolonged rest-cure, which alone can repair the damage to the brain-cells, are nearly all cured. It requires approximately the same length of time to recover from exophthalmic goiter as it does to recover from a nervous breakdown from other causes. A combination of surgery and an adequate rest-cure is, as I believe, the method of choice and will cure most patients.

My thesis is that the explosive exacerbation after operation is not due to the commonly accepted cause, such as escape of thyroid secretion into the circulation, but is due to injury to tissue and to fear, and that it may be prevented by excluding the psychic factor and by blocking the nerve-supply of the field with local anesthesia so that no impulse arising from injury of the operation can reach the brain. By this method even patients with advanced and otherwise hopeless cases of Graves' disease, abandoned by both the internist and the surgeon, may be operated on with safety and prepared for the maximum benefit from a rest-cure.

ABSTRACT OF DISCUSSION

Dr. A. J. Ochsner, Chicago: The work which Dr. Crile has done in connection with exophthalmic goiter, and the particular points he has mentioned this morning, are of sufficient importance to be borne in mind by all who deal with this condition. Especially is it important for us to remember that many of the conditions, which we formerly considered of most importance as causes of postoperative hyperthyroidism, are really of no special importance. In exophthalmic goiter we have a very severe destructive condition, which is due to the hyperthyroidism to which the patient has been exposed. Undoubtedly, most human beings are capable of neutralizing a certain amount of hyperthyroidism without having the tissues of the nervous and circulatory systems materially affected. In our normal bodies there is a condition of balance, so that the destructive effect of hyperthyroidism is not apparent. On the other hand, let one of us become exposed to an unusual strain of the nervous or physical system and immediately this balance may be destroyed and we may show the effects of this hyperthyroidism, particularly in the heart and nervous system. Tachycardia and the other well-known symptoms may appear. When we come to operate on these patients suffering from exophthalmic goiter, we deal with a condition of poisoning of these important structures, and by the addition of a very slight amount of further poisoning the balance is entirely overthrown. Whether in any given case this can be occasioned by the mental condition, or by a slight physical trauma, or by expressing into the tissues in the region of operation a certain amount of thyroid fluid, we do not know, but we do know that when the patient is overburdened with one or several of these conditions hyperthyroidism results. Any one of these conditions may produce an additional amount of hyperthyroidism, which makes the operation a dangerous one. It is only by eliminating, so far as possible, all the additional burdens placed on the patient that we avoid danger, and unless we do so we are bound to get the effect of excessive hyperthyroidism. I have discarded the operation under local anesthesia entirely except for the ligation operation. Möbius claims that the mental strain of local anesthesia is greater than the physical strain of general anesthesia, which seems reasonable, and in my work I have actually found that general anesthesia is harmless to the patient. The manner in which we accomplish this is to anesthetize the patient absolutely with ether given by the drop method; then we place her in the inverted Trendelenburg position, so as to produce an anemia of the brain, and perform the operation without giving any further anesthetic. The patient does not complain of any pain or discomfort afterward. In this way we protect the patient against two of the sources of physical and mental depression, and I believe that we have succeeded in that way in eliminating hyperthyroidism to the greatest possible extent.

There is one other point which Kocher brought out, namely, that of local absorption, and in two instances in which I did not provide for free drainage, there was hyperthyroidism. The thing I wish to impress on you particularly is that we must not try to eliminate this, or that, or the other cause, but that we must eliminate every possible cause that might do harm to anyone.

Dr. Archibald MacLaren, St. Paul: Dr. Crile is correct in his statement that the element of fear enters very markedly into the dangers of the operation for exophthalmic goiter. Whether other causes, such as hyperthyroidism, may or may not play a rôle, fear is a very decided element, and without doubt increases the mortality of the operation cases. I have employed Dr. Crile's suggestion of putting the patient to sleep without her knowledge, and since then I have not seen any hyperthyroidism. By not letting the patient know when the operation is to be performed, and by giving a volatile oil preliminary to the anesthetic as a "treatment," say the day before, and gradually coming to the administration of ether, the patient is anesthetized without her knowledge and, I am sure, does much better.

Dr. Martin B. Tinker, Ithaca, N. Y.: Dr. Crile manipulates the gland very carefully and skilfully, and this undoubtedly has been a factor, and an important one, in his results. I would like to bring up one or two points in this connection: Dr. Crile states that he has not seen hyperthyroidism resulting from handling of the gland. I have in my records several cases of hyperthyroidism from handling during examination; in one patient in particular the temperature went up to 103 F. after examination only, and I believe with no other factor than the handling to account for it. A second point brought out by Dr. Ochsner is the importance of drainage. I do not know any man who does much of this work who does not provide for proper drainage. If the dangerous symptoms after operation are from psychic causes only, why should we drain?

Another point which deserves extra emphasis is the preliminary careful examination of the patient. Success in the severe forms of exophthalmic goiter depends very largely on our ability to estimate what the patient can stand. I have been accustomed not only to do the preliminary ligation, but to divide the operation, if necessary, into several stages. In certain cases I have operated in as many as five stages, first ligating the superior thyroid, then exposing the gland, next removing the gland, then closing the wound, and in certain cases I have added another step, that of ligating the inferior thyroid vessels before removing the gland. Since attempting this stage operation I have done over one hundred consecutive thyroidectomies in bad cases of exophthalmic goiter without loss of life. I believe that this factor, the careful estimation of the condition of the patients, doing just what they can stand and no more, is extremely important.

Dr. Crile implies that general anesthesia is used by Dr. Mayo, but all who have seen him operate know that Mayo now uses local anesthesia in many of his ligations. I believe that local anesthesia is a very important factor in eliminating shock, and that with efficient local anesthesia it is unnecessary to use general anesthesia, at least in the majority of the cases. My experience since trying to estimate the severity of my cases more carefully and doing the operation in stages leads me to believe that these with local anesthesia are the most important factors in the results.

Dr. William R. Cubbins, Chicago: We ought to consider this thing from another standpoint, remembering its close association with the islands of Langerhans, the suprarenal capsule, the sympathetic system, and the hypophysis. The removal of the gland must be carefully considered, along with the mental effect produced on these very excitable patients. In addition to the Von Graefe sign, the tremor, rapid pulse and enlarged gland, I have observed that there has been a marked increase in the blood pressure, varying from 185 to 210 Hg. Immediately following an operation, the patients have uniformly stated that they were markedly improved, and complain of few, if any, of the original symptoms, while on examination we find the original symptomatology present with only a slight reduction in the blood pressure, say from 157 to 170. The pulse is still rapid, the eye prominent and the tremor marked. After eight or nine months there may be noticed a marked improvement of these symptoms, but I do not believe it is right to allow an inference to go out that in these patients operation is followed by immediate complete cure.

Dr. C. H. Mayo, Rochester, Minn.: Within the last few years I have written a number of papers on the treatment of exophthalmic goiter, and in nearly all, as I reviewed them later, I was reminded of a deformed child. I seem always to have attributed my success to some particular part of the technic which I do not now use at all. Once I used the Paquelin cautery to prevent absorption from the raw surface and the exudation of the serum. Next I used phenol and then Harrington's solution. Now I do not use anything on the gland, and in 800 cases my results have been just as good as they were when using the cautery and solutions named. In the early days the patients coming to the surgeon were in bad condition, often on the verge of death. Surgeons have come to recognize these cases and do not operate when the condition is hopeless. There are several types of goiter, and we should be able to recognize them.

In Rochester we operate on the gland itself by removing or ligating its blood-supply. We treat patients by cystolysis with a serum. By ligation we secure a change in the blood supply, and this change may come through other influences. There may be a tendency to recover in one-fourth of all cases. We ligate when we think that the patient cannot survive a radical operation for removal of all of the gland. This puts the fatal cases over into the ligation series. We have reduced our mortality greatly by exercising judgment in selecting the operative cases. If the patients are not in a suitable condition to be operated on, they are put under medical treatment until we feel that something can be done for them. We ligate, say, one artery to-day, another in a week or two weeks, and so on.

The choice of an anesthetic is not so important. I often use local anesthesia. I have had two deaths following the ligation of the thyroid artery, one under general and the other under local anesthesia. As Dr. Crile has stated, the psychic factor plays a great part in these cases. Patients with marked psychic disturbances are not suitable for any kind of an operation and they should be left in the medical class. We cannot always select the cases or make an exact diagnosis of conditions, but by carefully studying the patients and giving suitable treatment, we certainly can diminish the mortality very materially and also get much better results.

Dr. G. W. Crile, Cleveland: In Kocher's clinic there are certain patients with advanced exophthalmic goiter on whom he does not undertake to operate. He, like Mayo, found that if he operated in such cases the patient died, and the cause of surgery and the interests of the patient are not conserved.

I wish to suggest a method that will permit the surgeon to do a ligation on every patient who is still alive. The operation can be done in bed, in a minute or two, without pain and without reaction. The field can be cocainized without frightening the patient to death, as many patients with exophthalmic goiter have been. If fear is eliminated, and it can be done perfectly well, there will not be any trouble. When the brain is marooned, it does not appreciate that an operation is going on. Therefore, the patient must be kept psychically and physically in a negative phase. There is no reaction, and I believe, from what we have now discussed, that it is quite evident that we can do a ligation in any case. I do not say that all patients can be cured, because some of these cases are far advanced. I have operated on patients who have been on the verge of delirium. I have operated on them in bed without any reaction. It is not in the mild, recent cases, but in all cases, that the patients are benefited by ligations.

Knowing, as we do, that in exophthalmic goiter changes in the brain cells take place, how can we expect merely to operate on the glands and then submerge the patients again in an environment from which they received the disease and expect them to recover promptly? My idea is that the operation serves to break the pathologic chain that is enthralling the patient; that once broken, the patient may be cured by being compelled to take the rest cure. Operation is only one phase of the treatment. The rest cure and after-care are other phases, and it takes from two months to a year, or even more, before these patients can be said to be cured, and unless they are completely cured at the first trial they are more difficult to treat when a relapse has occurred. I have often seen cases which bear out this statement. Surgery should try so to perfect its technic that in every case, no matter how bad, the patient may be speedily operated on and benefited. Surgical treatment is only one step in a cure. A long rest cure must follow. This is as necessary in goiter as it is in a nervous breakdown from any other cause.

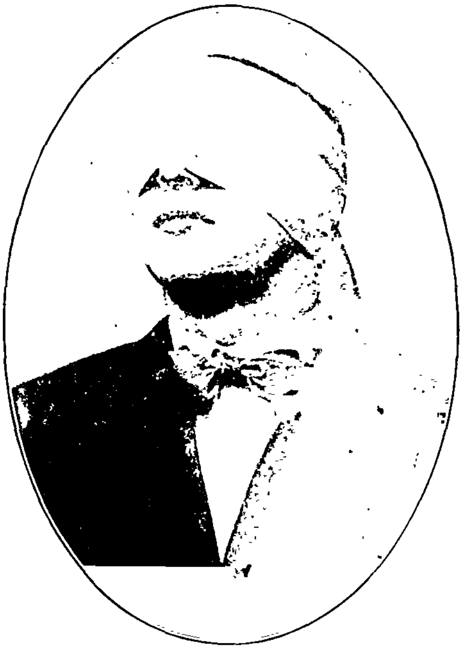
Fatigue in Neurasthenia.—Under normal conditions the sense of fatigue is not unpleasant, and if followed by timely rest may be a positive pleasure. If, however, effort is pushed to the point of complete exhaustion, symptoms are apt to arise which closely resemble those of neurasthenia. The individual becomes mentally depressed and indifferent to all other considerations but himself; effort of all kinds, physical or mental, is painful, he suffers from headaches, backaches, etc., and is irritable and sleepless. All these and similar symptoms, whether the result of physical or mental labor, depressing emotions, prostrating illness, etc., sooner or later yield to appropriate rest and régime.—D. Ferrier, in the *Practitioner.*

SODIUM CACODYLATE IN SYPHILIS

A SECOND NOTE

A. J. CAFFREY, M.D.
MILWAUKEE

I recently published[1] a report of a case in which a typical chancre was successfully treated with sodium cacodylate. Dr. L. L. Michel[2] questions the results. I therefore submit the accompanying portrait of the patient, taken Jan. 10, 1911. The dark part on the lip shows the location of a bleb-like elevation that was caused by the patient's drawing the lip under the upper teeth, to hide it when he was on the street, because he was ashamed of the chancre. The patient is well and healthy, has gained weight, and his kidneys are acting normally. He has no ocular signs of poisoning, and no return of the secondaries. He is apparently cured.



Patient treated with sodium cacodylate for chancre on lip.

I have been using the sodium cacodylate side by side with 606 and while I am glad to say that I have had good results with 606, I have had just as good with sodium cacodylate. Dr. Michel, in his letter[2] to The Journal, tells of chancres on the lip and elsewhere healing under the influence of the soluble salts of mercury in two weeks, or thereabouts. I do not doubt this, as I have had the same result myself with mercury, but mercury is just what we are trying to get away from. I find that patients tolerate sodium cacodylate well and its toxic effect does not show until after very strenuous treatment. Dawes and Jackson[3] found that it required 0.8 gm. injected to kill a rabbit; in the case reported I have given in all, over a period of one month, 46 grains.

600 Grand Avenue.

A PLEA FOR GREATER CARE IN ARRANGING PATIENTS ON THE OPERATING-TABLE FOR THE PREVENTION OF THE COMMON POSTOPERATIVE WEAK BACK

THE PRESENTATION OF AN APPARATUS FOR HOLDING THE LITHOTOMY POSITION WITHOUT STRAIN

JOEL E. GOLDTHWAIT, M.D.
BOSTON

In a previous paper[1] I called attention to the importance of considering the positions in which patients are placed during the performance of operations so that the sacro-iliac joints and the lumbar spine cannot be strained.

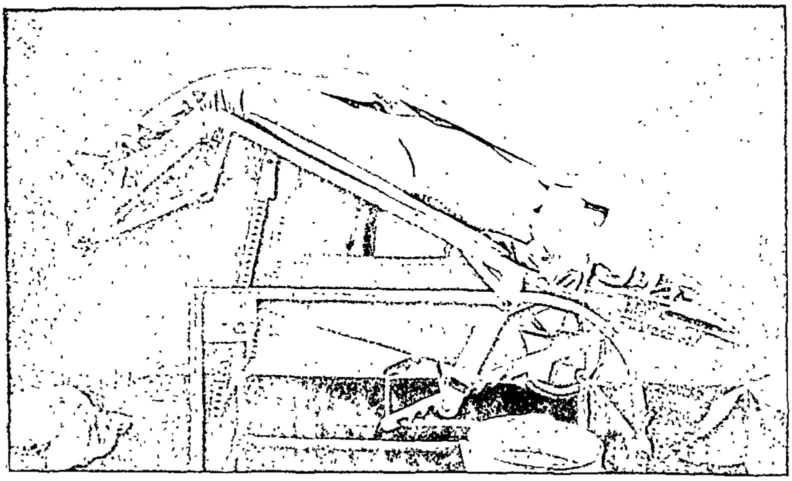

Fig. 1.—Faulty position without support for the back and with the thighs hyperextended. Strain of the lumbar spine and sacro-iliac joint must result.

The facts that such strains do often occur and that many patients are harmed because of these unnecessary strains in connection with operation cannot be questioned; but only those who have to do with the treatment of weak or painful backs or with chronic joint diseases in adults can appreciate how frequently such conditions occur.

In the article referred to the position in which the patient should be placed, if the operation requires the horizontal position on the back, or the Trendelenburg position, was shown, as well as the undesirable position in which strain of the lumbar spine and sacro-iliac joint are possible, and because of the apparent importance of the subject, this section of the previous paper is quoted:

"We must remember that, when lying on the back, if the bed or supporting structure is hard so that the buttocks cannot settle into it, the lumbar spine must sag downward, and if the buttocks are large or the waist small, the amount of this sag may be enough to cause painful strain on the interspinous ligaments or on the sacro-iliac joints. . . . .

"This means that in planning operations we have responsibilities other than those which have to do with the purely local lesion. At such times, if the whole body is considered, the strained sacro-iliac joints with the distressing backaches and with the not infrequent disability which results from this will not occur. The patient will not be put on the table as shown in Figure 1, since in this position the thighs are hyperextended, the axis of the pelvis must be drawn forward, thereby raising the upper part of the sacrum and the lumbar spine. There being no support for the spine, however, it must sag back again, and with this the sacrum must be dragged downward, the two influences necessarily resulting in definite strain of the sacro-iliac joints, with subsequent backache. Not only this, but as the result of the hyperextension of the thighs and the tilting downward of the anterior part of the pelvis the abdominal muscles must be stretched, making unnecessarily difficult the separation of these muscles during abdominal operations. With the slight support under the back to prevent the sag of the spine and also under the knees so that hyperextension is prevented (Fig. 2), all of these undesirable features can be overcome without in any way interfering with the important elements of the position."

In regard to the protection of the patient when the operation calls for the lithotomy position, while the desirable position as well as the common undesirable position was shown, it was quickly realized that the maintenance of the desirable position was practically impossible with any of the resources at our command. Because of this the apparatus which is here described was designed, and it is the presentation of this that has seemed to me a sufficient justification for the communication.

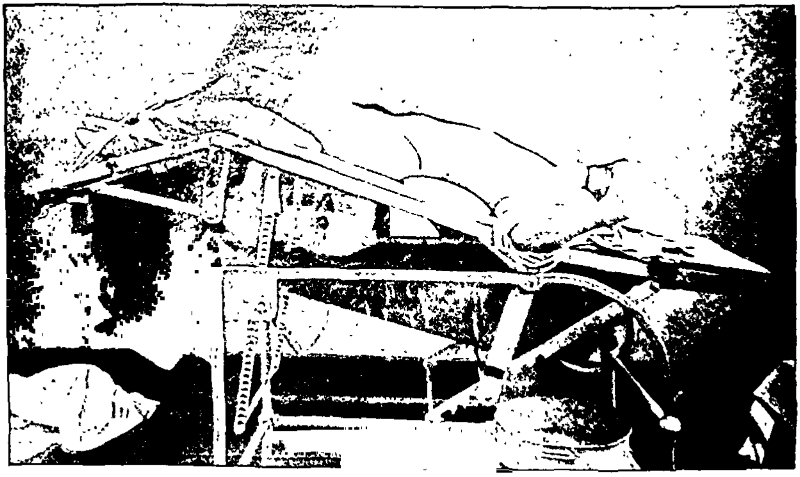

Fig. 2.—Correct position, with lumbar spine supported and with pillow under knees to prevent the hyperextension. No strain of the lumbar spine or sacro-iliac joint can result under these conditions.

In studying the subject I have been impressed by the fact that not only do the patients often receive harmful strains of the back by being placed in these positions, but the assistants at such operations are often severely strained and unnecessarily exhausted because of the positions which they are forced to assume—positions which no human being can maintain for long without harm. The frequent giving out of the assistants at such operations while the operator himself remains fresh, in my studies has made me try to devise something that would not only protect the patient, but would protect the assistant also.

---

[1] The Relation of Posture to Human Efficiency and the Influence of Poise on the Support and Function of the Viscera, Boston Med. and Surg. Jour., Dec. 9, 1909.

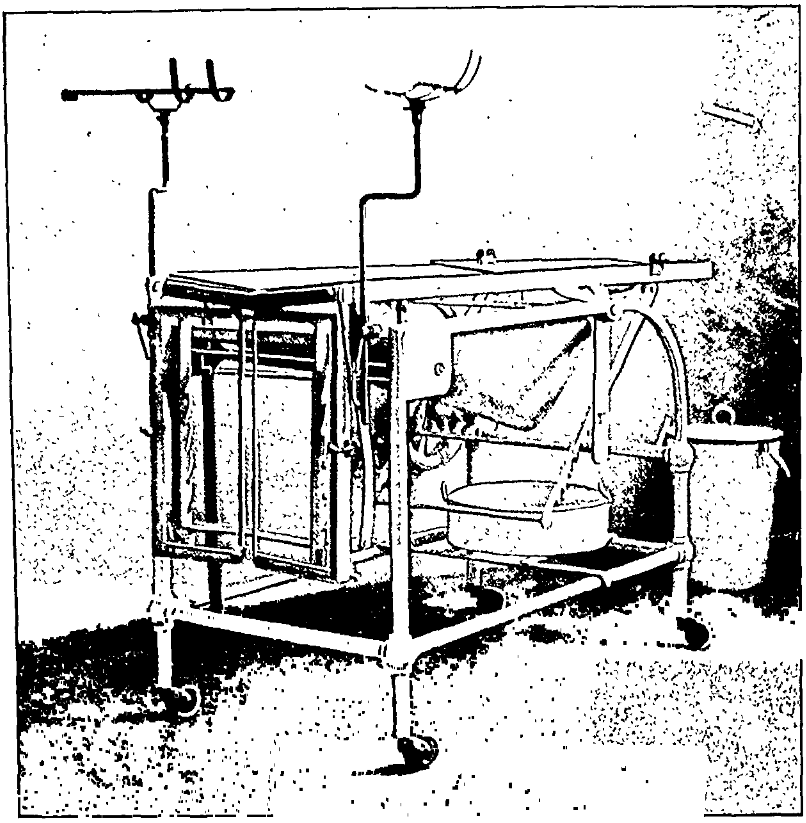

Fig. 3.—Table with adjustable leg supports.

To quote again from the article above mentioned: "With the lithotomy position, also, there is a right and a wrong way of obtaining this. If the thigh is sharply flexed and at the same time abducted, and if, as is so commonly seen with this, the assistant rests on the leg as he reaches over to assist the operator, the ilium must be strained downward and backward, with resulting sacro-iliac strain and weakness." If, however, the thigh is flexed less sharply and if a bandage or strap is attached about the knees to prevent the marked separation of the knees, "the position can be maintained indefinitely without harm and without sacrificing the essential features of the position."

The same opinion is held to-day in the present comment as at the time of the presentation of the earlier paper, but I now realize fully that, while the position last mentioned is the desirable one, it cannot be maintained without definite mechanical aid. The strap about the knees to prevent the extreme abduction of the thighs in the first place, interferes with the usefulness of the assistant, and when the coverings are in place unnecessarily obscures the field. In the next place, to hold the leg in this position for the length of time of the usual operation is absolutely impossible, since the weight of a leg is no small thing and since no muscle even under favorable conditions (and this would be decidedly unfavorable) can maintain its contraction for more than a very few minutes without becoming wearied and relaxing. This must result if the assistant attempt to hold the leg, and it not only allows ultimate drag of the leg, but represents a source of unnecessary strain for the assistant.

To overcome this the leg-rest that is shown in Figure 3 has been constructed by the Kny-Scheerer Company and can be secured through them for attachment to any table. It consists of the flat rest on which the lower leg is placed, and the adjustment of the position of this is made by raising or lowering the upright, for the height, or by rotating the upright so that the double angle moves the rest farther away or nearer to the patient. When the leg is once placed in the desired position (Fig. 4), the position cannot be changed except as the operator may wish, and not only this, but the assistant has a definite rest on which he can lean without harm to the patient. In this way the extreme weariness of the assistant, which must come when the body is used in the flexed and partially rotated position with only the muscle supports to protect it, is entirely eliminated.

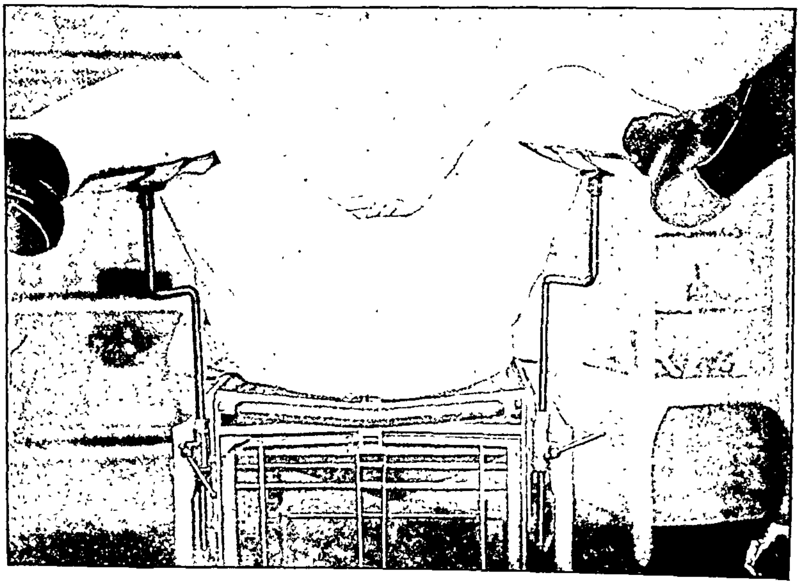

Fig. 4.—Lithotomy position, with legs supported on the rests shown in Fig. 3. Once arranged, the position cannot change except as the surgeon may wish.

The effect on the position of the thigh which results from trying to support the leg on the upright commonly attached to operating-tables, in which the leg hangs by a noose around the ankle, is shown in the left leg of

Figure 5. This must result in the sag of the legs apart, with at the same time the outward rotation of the thighs, both positions meaning strain to the pelvic joints, which must be greatly increased if the weight of the assistant is added. The contrast to the position of the right leg in this illustration is at once apparent.

In the experiments which were made in planning the leg rest I myself took the positions in which the patients are commonly placed, and if anyone has any question as to where the strain is received I would suggest that that person make the same experiment on himself.

In conclusion I wish simply to call attention to the fact that the position in which the patients are placed at the time of operation has much to do with the presence or absence of postoperative backaches and the subsequent weakening of the sacro-iliac joints. The positions in which strain will not take place are so easily obtained that there is no possible excuse for such harmful conditions occurring. An apparatus is shown in which the lithotomy position can be maintained indefinitely without strain either to the patient or the assistant.

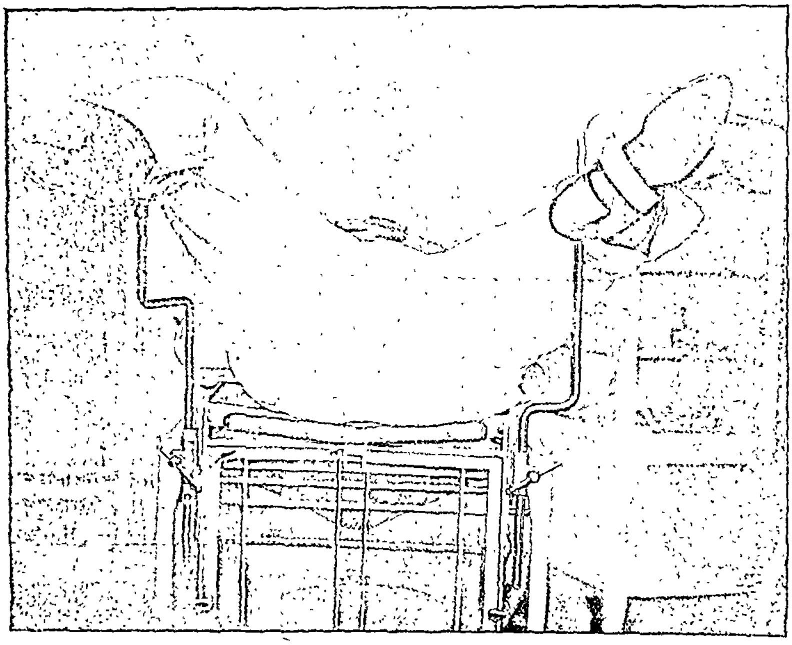

Fig. 5.—The right leg correctly supported, the left supported by the ankle noose which must allow sag and joint strain.

372 Marlborough Street.

Plague Eradication and Rats in India.—In one house in Belgaum 197 rats were caught in the course of a year; this was a grocer's shop in the city market. It was a small house of three rooms, occupied by six people, Mahomedans, and it is a curious fact that the house possessed two cats. There were seventeen houses in which more than fifty and less than a hundred rats were caught; nine of these were ordinary dwelling houses, two were grocers' shops, one a grain godown, two liquor shops, one butcher shop, one stable, and one weaver's house. Two hundred and thirty-seven houses yielded a catch of more than twenty but less than fifty rats. Twenty-four of these were grocers' shops, sweetmeat sellers or grain stores, nineteen were weavers, eight were tailors' shops. No other trade seems to possess any influence especially favorable to rat infestation. The Indian cat is not a particularly good rat catcher.—Reports on plague investigations in India.—*Journal of Hygiene.*

INTRACRANIAL SURGICAL LESIONS IN CHILDREN *

CASSIUS C. ROGERS, A.M., M.D.
Professor and Head of the Department of Surgery in the Chicago College of Medicine and Surgery, Medical Department of Valparaiso University; Surgeon to Frances E. Willard Hospital.
CHICAGO

I wish to present a series of cases consisting of different cranial and intracranial lesions, giving brief history, the operation performed and the indications for surgical interference, as well as the results obtained. Although in this series the results have not been so flattering as one would wish, I hold the long existence of the lesion responsible for producing destruction irreparable by surgery.

The best results in surgery are achieved by prompt action, and the surgery of the brain is no exception. When once areas of the brain are destroyed we can hope but little for repair. Many of my patients are brought to me when all hope for improvement has been abandoned months and even years after.

Most of the patients have been given potassium iodid for long periods, and perhaps several periods, no results having been obtained. Physicians have been changed and another course of potassium iodid given, when three and at most six weeks should have given positive proof that the treatment was of no avail.

If a child had a broken arm, what physician would wait twelve weeks to reduce it or wait until an abscess had formed, as was done in the skull fracture in Case 12? This also should remind us of the disasters that may happen weeks after an apparently slight head injury.

Early surgical interference in fracture of the skull, with intracranial hemorrhage, will be rewarded by almost certain recovery (Case 2), while delay for months or years hoping against hope that the focal symptoms if present will disappear, can lead only to discouragement and disappointment after operation (Cases 3 and 4). Much improvement may, however, be obtained in children after several years' delay (Case 5). Constant localized headaches should demand our most serious attention and our greatest efforts to determine the cause, as they may mean localized diseased areas within the skull (Case 6). Severe headaches following chronic otitis media associated with dizziness, rapid rise and fall of temperature, nausea and vomiting, frequently demand prompt surgical interference (Cases 7 and 8) to prevent extension into the cranial cavity.

I have studied carefully a number of children with impaired mental development, endeavoring to learn what was the cause of the mental defect and what benefit could be derived from medical and surgical treatment in these cases. Many children, soon after birth, suffer from malnutrition, probably from some unknown hereditary cause. Many of these cases improve under medical treatment while others seem to be benefited but little, or not at all. It is the latter class that I wish to report.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-first Annual Session, held at St. Louis, June, 1910.

These children frequently have convulsions from twenty-four hours to a week after birth, associated with slight rise in temperature and apparent unconsciousness. After the attack they fall asleep for several hours, the attack being repeated at indefinite periods. These attacks may be associated with involuntary movement of the extremities or face. Home treatment is resorted to. The parents discover later, however, that the children are not so bright as other members of the family, or children of the same age in other families, and it is then that the family physician is told of the symptoms the child presents. Frequently there is a tuberculous tendency in the family, but more frequently there is a syphilitic taint. Many of these children improve under antisyphilitic treatment, but if the improvement is temporary it is not conclusive evidence that the underlying cause is not syphilitic, for many of these children will not tolerate antisyphilitic treatment, nor will they be benefited if it can be tolerated. I have found in these cases, capillary arteriosclerosis as early as the sixteenth month, the findings and symptoms of these children indicating intracranial pressure. Not until the pressure has been relieved will the administration of mercury or potassium iodid prove beneficial; but many of these patients seem to make marked improvement after decompression, followed by antisyphilitic treatment.

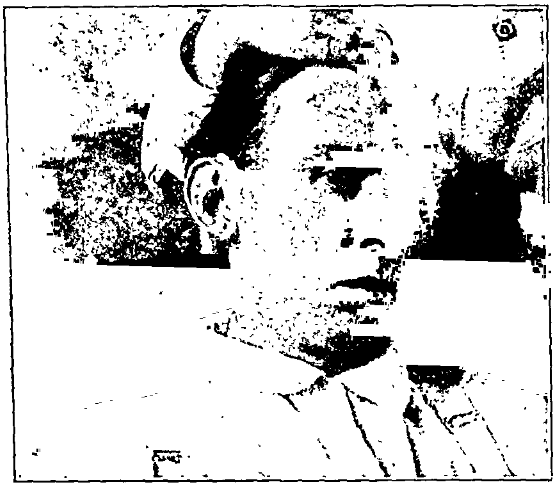

Fig. 1.—Patient 4, just before operation. Decompressed fracture, duration fifteen years.

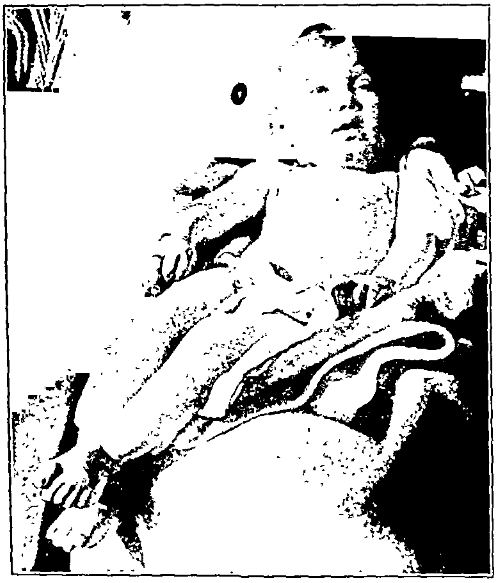

Fig. 2.—Patient 10, before operation.

In cases of chronic tuberculous meningitis the children have not improved after operative interference, while in chronic syphilitic meningitis every patient has apparently improved under antisyphilitic treatment after decompression.

It is my rule to make a Wassermann test in all cases, and if it is found positive or questionable to repeat the test, and also make a test on both father and the mother. I have not failed in a single instance, when I secured the positive test in the baby, to find either the father or mother giving a like test.

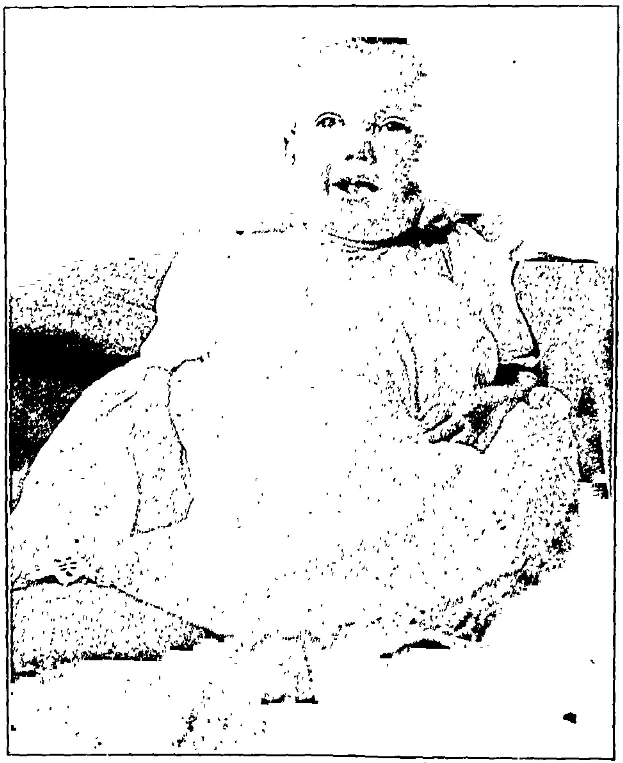

Fig. 3.—Patient 10, two months after right and left temporal decompression, showing bulging in temporal region.

Cases 9, 10, 11, 12 and 13 are selected from a series representing the above class of cases. In all cases of suspected brain tumors, if the tumor can be located, operation should be done with the hope of removing the tumor or relieving intracranial pressure, trusting that the tumor can later be removed. The decompression must be done before the patient has advanced ocular or mental disturbance (Case 14).

Children presenting, soon after birth, paralysis of a hand or leg should be closely watched and if the paralysis progresses and there are signs of intracranial pressure or rapid extension producing progressive paralysis, much, I think, may be done in the way of benefiting and saving the lives of these babies, if a large opening is made in the skull and intracranial pressure relieved (Case 15).

Following is a brief history of the cases referred to above:

Case 1.—*History.*—R., a girl aged 6, American, entered hospital Oct. 28, 1906, at which time she had been sick six weeks with headache and some fever; diagnosis, typhoid fever. The patient improved slowly only to relapse again to her former condition. Family history negative; the patient had had usual diseases of childhood; measles at age of 4; father living and well, aged 50; mother living and well, aged 50; has four brothers and four sisters. On the afternoon of Oct. 28, 1906, the patient's headache became severe and she became stupid and then unconscious. At this time her condition was so grave that she was taken to Willard Hospital, arriving there about 3 a. m., where I first saw her. Six weeks before becoming ill she had slipped on the deck of a boat while returning from England, striking her head against a bolt-head, but little thought was given this and no medical aid sought. She complained of headache a few days; then was apparently as well as usual.

Examination.—At the hospital, pulse was 60, respiration 10, temperature 98.5. Blood-count showed hemoglobin 78, reds 3,400,000, leukocytes 26,000, polymorphonuclears 80. A diagnosis of intracranial pressure was made.

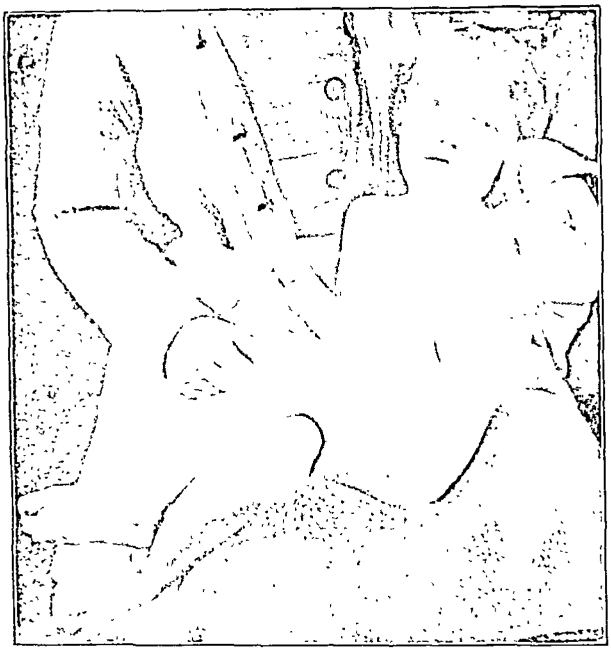

Fig. 4.—Patient 11, before operation, showing crossed and spastic condition of lower extremities.

Operation and Result.—Under chloroform anesthesia, a large subdural abscess was drained. The time consumed was forty minutes. The patient improved until the tenth day when she had a chill, rapid rise of temperature and died on the twelfth day following the operation. Temperature per rectum was 106.6, pulse 138, respiration 60. The post-mortem findings were diffuse meningitis, and double pneumonia.

Case 2.—*History.*—F., a boy aged 7, American, entered Willard Hospital July 6, 1908. Family history negative; had had measles and scarlet fever. July 6, 1908, patient fell from a stairway to a cement floor, a distance of about eight feet. He was unconscious when picked up but remained so only a few minutes. After regaining consciousness he appeared perfectly well for about forty-five minutes; then gradually relapsed into unconsciousness and remained so. This was accompanied by vomiting and muscular twitching, followed by violent involuntary muscular contractions of the entire body. The pupils were widely dilated; there was a large swelling in left parieto-occipital region. Dr. W. J. Butler first saw the patient and brought him to the hospital at 8 p. m., two hours after the injury. I first saw him at 5:30. Diagnosis was fracture of the skull with hemorrhage.

Operation and Result.—Patient was taken to the operating-room at once. A large bone flap was reflected; there was no extradural hemorrhage, but a large intradural hemorrhage filling the subdural space; the dura was opened and a large flap turned up. Bleeding points were ligated with fine catgut. The wound was closed without drainage. Time of operation and preparation was forty minutes; anesthetic, chloroform. Patient awoke from the anesthetic conscious, made an uninterrupted recovery and left the hospital on the tenth day cured.

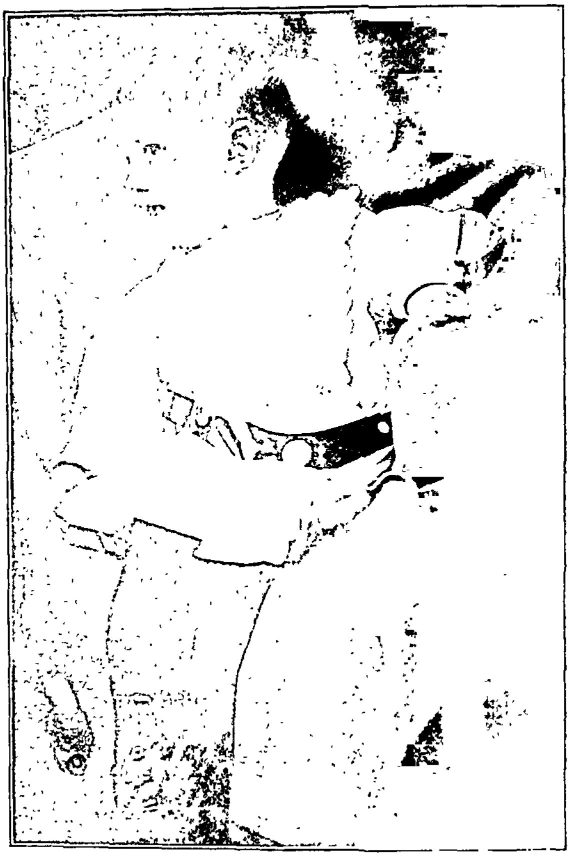

Fig. 5.—Patient 11, two months after operation. Able to sit up and hold head erect. The head is not leaning against the back of the chair.

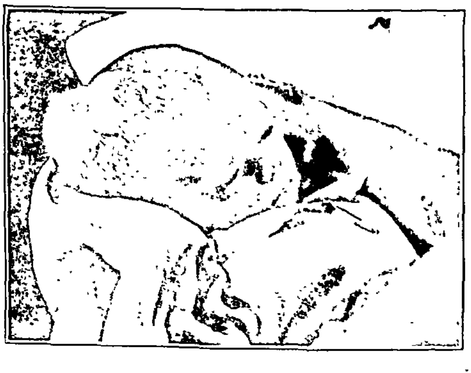

Fig. 6.—Patient 16. Baby 2 weeks old. Infected cephalematoma, drained and cured.

Case 3.—*History.*—Miss P., Polish girl aged 15, entered Willard Hospital Nov. 5, 1908. Family history negative; patient had had usual diseases of childhood. Two years before while watching a parade patient jumped off the back porch to a cement sidewalk, a distance of about 15 feet. She fell on her side, striking the right side of the head against the walk. She was unconscious for a short time. On regaining consciousness she had a paralysis of the left leg and arm which grad-improved for about six months, after which there was no ovement. At time of admission she could not walk and l not use the left arm or hand. Examination revealed a essed fracture in the right parietal region.

eration and Result.—A large bone flap was raised; dura found adherent to other coverings of brain and the brain ; the bone flap was replaced without drainage. The an- etic used was chloroform; time of operation, one hour. ent has improved enough to walk with a cane, but the arm is little benefited.

ASE 4.—*History.*—W., a man aged 21, American, family ory negative, was kicked by a horse in left frontal region he age of 7. The physician at this time removed a num- of pieces of bone, and some brain tissue was lost. Wound ed, leaving a large pulsating wound. At the age of 14 the ent developed epilepsy and had frequent and severe attacks. entering the hospital the attacks were as frequent as sev- a day.

peration and Result.—Large skin flap made and a large unt of depressed skull removed. Wound was closed with- drainage. The time of operation was about one hour. sthetic, chloroform. Patient developed pneumonia and l on the fifth day following the operation.

ASE 5.—*History.*—C., a boy aged 4, entered Willard Hos- l March 15, 1909. Mother says he was a large baby, labor ; and difficult. She was finally delivered with instruments. y seemed well and the physician noticed nothing wrong, the child cried a great deal and did not move his arms and as did her other two babies when they were young. The her said that the child never made any attempt to use his hand. The physician informed her that in time the would be used. At 6 months the mother discovered that left arm and leg were paralyzed. The baby always lay on back, never attempting to sit up. He cried nearly all the e he was awake. At the age of one year he still made no empt to sit up. At this time a physician was consulted l the mother was informed that the baby was paralyzed on left side and the paralysis would be permanent. At the of 16 months the mother laid him face downward and he rned to pull himself along with his right hand, pushing h his right leg and foot. He first sat up when he was 2½ rs old and would hop about, using his right leg and arm. is was his mode of travel when I saw him in the hospital. could stand on his right foot if supported, or could get ld of some object, as a chair, table, etc. He had never ked, nor could he be taught. His temper was violent and at times would beat his head against the floor.

Examination.—The left arm showed nothing abnormal except ophy. The left leg was atrophied and the patient had a ked talipes varus.

y physicians had been consulted and none gave the any hope, but the mother consented to the request of inger (to whom I am indebted for the case) to allow rate and see if there was pressure that could be

n and Result.—March 16, in my clinic at the Wil- tal I turned back a large bone flap on the right side extradurally several large deposits of lime salts. peeled off like fish scales. The dura was then nothing pathologic found. The bone flap was re- d in about one week the child began to n a little. He left the hospital at the end of the able to stand with the aid of a stick used as a sup- ter from his mother recently says that he is talking can walk well without any assistance. His great w is the club-foot. This case was undoubtedly one l hemorrhage following injury by the forceps. The rtially absorbed; the rest calcified. Had this n operated on when a few weeks old there is no the result would have been more satisfactory than n date—four years after the injury.

tory.—An American girl aged 18, family his-

had by the baby carriage falling down a series of steps turning over, throwing the child on the stone walk on its head. That child's skull was trephined and the bleeding vessel was ligated. The paralysis was relieved and the

Treatment and Result.—The head of the femur was resected, but the sinus did not close. One year later I amputated the left lower extremity at the hip, as the *x*-ray showed necrosis of the femur and there were multiple discharging sinuses in the thigh. The wound healed nicely but soon the left elbow became swollen and painful and a sinus developed, communicating with the lower end of the humerus. This was curetted and the external condyle chiseled away. This healed and in a few weeks the patient developed a temperature of 106, respiration 60, with rigidity of the neck, and head drawn back. A diagnosis of tuberculous meningitis was made. She improved, temperature reaching normal in six weeks, but with a rise in the evening around 102. All this time there was severe occipital headache. As the pain was constant and localized I trephined and removed a necrosed plate of skull 2 inches by 2½ inches from the parieto-occipital region. Before this was healed, a mastoiditis developed on the right side and later a mastoiditis on the left side. Both were operated on and healed. The patient has had in all thirteen operations and has had tuberculin injections for eighteen months. In June, 1910, she was in better health than at any time since I first began to treat her, five years ago.

This patient has had right and left mastoiditis, with an extradural abscess in the parieto-occipital region.

CASE 7.—*History.*—P., a French boy aged 9, family history negative, entered the Willard Hospital, Dec. 13, 1909. Six weeks previously he complained of pain in the left ear, which was treated, and after a paracentesis of the tympanum he improved rapidly and the physician was discharged. A few days later the boy complained of frontal headache. This was accompanied by vomiting and dizziness. The following day the headache was more severe and the dizziness and vomiting worse, but the patient complained less, appearing stupid. About 4 a. m. December 13, the parents could not arouse the patient to give him his medicine. He was brought at once to the Willard Hospital, when I first saw him, with his attending physician, Dr. Stoll. A diagnosis of intracranial abscess was made.

Operation and Result.—The mastoid antrum was opened and the skull trephined just above the mastoid. About a dram of pus escaped; a gauze drain was inserted and the usual dressings applied. The patient soon regained consciousness and made an uninterrupted recovery, leaving the hospital in two weeks.

CASE 8.—*History.*—M., boy aged 9, American, family history negative, two months previous to entering the Robert Burns Hospital, Feb. 20, 1910, had acute otitis media. His physician, Dr. Brode, went South for a rest and the patient received no medical care until the evening of February 20, when Dr. Stewart was called and found the patient suffering excruciating pain, terrific occipital headache and at times apparent delirium.

Operation and Result.—At the hospital the mastoid antrum was opened and found full of pus. The lateral sinus was exposed and a few drops of pus could be seen oozing from the skull along the sinus. A probe was passed along the sinus and pressure made against the sinus when a large quantity of pus was liberated. A plate of the skull was now removed just above the sinus and a large extradural abscess drained. Patient made a good recovery and left the hospital in ten days.

Cases 7 and 8 will, I am sure commend to all of us the advisability of removing large plates of skull in draining abscesses, either intradural or extradural.

CASE 9.—*History.*—Infant A, aged 3, American, family history questionable, had a normal rapid delivery; a few hours after birth the nurse noticed that the baby acted strangely and thought that it was having a spasm. The physician was informed and the next day the baby developed a high temperature and became unconscious, remaining so for five days. It then improved but had some paralysis of the left upper and lower extremities. This improved but the baby frequently had apparent convulsions. Soon the lower limbs became crossed, the left anterior to the right and the legs and arms were very rigid. The baby never sat up, never talked, would not chew

or three days, liquids. At the age of 3 when I first decided just what must be done. If you are in a hu
them alone.

mann negative. Blood-count showed no change in number of leukocytes.

Operation and Result.—April 9, 1910, a large occipital bone flap was reflected and the cerebellum exposed, but no tumor could be located. A plate of bone two inches square was removed and the headache entirely disappeared; also the nausea; but both have returned and there has been no permanent relief from the operation; a second operation has been refused.

CASE 15.—Infant G., aged 36 hours, Jewish, born after thirty-six hours' labor (instrumental delivery), was resuscitated with difficulty; scalp lacerated in right parietal region; left arm paralyzed; child in a stupor; later left leg became paralyzed. I advised operation which was refused. Baby died thirty-six hours after birth.

Autopsy showed depressed skull fracture with edema of the brain and membranes in the right motor area.

What might have been accomplished by operation in this and similar cases experience only can enlighten us.

CASE 16.—A baby 2 weeks old developed soon after birth a large fluctuating tumor on left occipital parietal region diagnosed as cephalematoma. On the tenth day the baby developed a temperature of 104 F., which continued until the contents of the tumor (an infected hematoma) were evacuated, after which the temperature dropped to normal and remained normal.

ABSTRACT OF DISCUSSION

DR. E. H. ABBOTT, Elgin, Ill.: Of four patients referred to Dr. Rogers by myself and operated on this year, one died of surgical shock; two have shown more improvement than he has given them credit for; one showed no improvement, but the younger child on whom he did a double decompression had very little vision before the operation and sight has improved to such an extent in this short time that it can recognize food across the room. The older child, four years old, this child's brother, has an asymmetrically developed skull due to a unilateral hydrocephalus. Dr. Rogers aspirated the lateral ventricle in this case, as well as doing a decompression operation. The time has been insufficient since that operation for us to judge the amount of improvement, but two of the four operated on show decided improvement.

DR. C. G. KERLEY, New York: One feature of these cases of operation on the brain in children that I have observed is the indefiniteness in determining the ultimate results. I had that illustrated in one case, in which a baby was injured by the baby carriage falling down a series of steps and turning over, throwing the child on the stone walk on its head. That child's skull was trephined and the bleeding vessel was ligated. The paralysis was relieved and the child made a temporary recovery. Then there developed paralysis of one side of the body, but the child developed beautifully mentally up to ten years of age. The result of the operation was remarkable considering the work that had been undertaken. The boy had a fairly good arm and a fairly good leg on the paralyzed side, and was in excellent mental condition until, at 10 years of age, he developed epilepsy. I have advised a second operation. This case has impressed on me the indefiniteness of results in these cases, for the epilepsy may develop years after an apparently successful operation. Our results in removing so-called pressure in cases of spastic paralysis several years ago were universal failures.

DR. CASSIUS C. ROGERS, Chicago: I would like to ask the last speaker if in the decompression operation the dura mater was opened. In children the dura mater has the power of forming skull and unless that is opened the decompression is temporary. In the cases I have reported the results have been encouraging. The patients are as well off since the operation as before, and in most of the cases there is improvement. In every case of intracranial hemorrhage, if operation is done in time, there should be a good result. We would not delay, if the hemorrhage were in the abdominal cavity, to open and tie the vessels, so why should we wait when the condition is in the cranial cavity? Epilepsy may develop twenty or forty years after an injury to the head. I have been operating on such patients for about ten years and I have had no epilepsy follow the operative procedure if the patient did not have epilepsy before the operation, and I have operated in cases in which the patient had had repeated attacks of epilepsy before the operation and have been free from these attacks for seven years. The case sent me by Dr. Abbott, in which I introduced a trocar and drained the lateral ventricle, I forgot to mention. We do not know what the end-results will be in any of these cases. Undoubtedly there are many children in insane asylums an[illegible] homes for feeble-minded children, whom an operatio[illegible] ound time would have benefited; it would have kept them [illegible] these institutions. There are many individuals [illegible] ould institutions who are there because they have [illegible] t ensued, injuries followed by abscess, etc. A year or [illegible] l F. The operated on a man who had served two periods in [illegible] some diffi- and I found an abscess the size of a hen's egg. [illegible] paralysis of dural abscesses are not uncommon. *To diagn*[illegible] xtremities were *children the only thing to do is to watch* [illegible] e obtained only *sit by the bedside and watch them for h*[illegible] as traction of *spend nearly all of your time with them, pe*[illegible] m. on *or three days, until you have made your diag*[illegible] *decided just what must be done. If you are in a hurry, let them alone.

EXPERIENCE WITH SALVARSAN

EHRLICH-HATA'S 606 IN THE NEW YORK SKIN AND CANCER HOSPITAL

HOWARD FOX, M.D., and WILLIAM B. TRIMBLE, M.D.
NEW YORK

Through the kindness of Dr. Flexner of the Rockefeller Institute we received in October twenty tubes of Ehrlich's 606 for experimental use in the Skin and Cancer Hospital. The twenty tubes have been used for the treatment of eighteen patients, a second injection having been given in two of the cases in which relapses occurred. All of the patients remained in bed at least three days after treatment and then continued under observation at the hospital or returned to the dispensary at weekly intervals. All except two of the patients have remained under observation up to the present time.

With the exception of a patient with nodular leprosy to whom the new remedy was experimentally given, the patients selected for treatment were those who presented active syphilitic manifestations and (except in Case 8) a positive Wassermann reaction. The choice of patients was limited to those in whom ophthalmoscopic examination of the fundus and examination of the heart and urine showed no deviation from the normal condition.

The injections[1] of salvarsan were given either in suspension or in solution in doses varying from 40 to 60 centigrams. In the first nine cases the drug was given in a neutral suspension in the subcutaneous tissue of the interscapular region. In one case (10) the injection was made in the quadratus lumborum muscle. In the last ten cases, soluble injections were given in the gluteal muscles, according to the method of Lesser.

Examinations for *Spirochæta pallida* were made with the dark-field illuminator in five of the cases and showed a rapid disappearance of the organisms after injection. In no case could any spirochetes be found at the end of seventy-two hours after treatment, as seen in Table 1.

The Wassermann reaction was performed in every case before the injection was given and was afterward repeated at weekly or somewhat less frequent intervals. It was found to be positive in all except one case (9) in which mercury had been previously administered for several months. The original Wassermann method was performed by us, using two antigens for every case, one of the antigens being an alcoholic extract of syphilitic liver that had been found reliable in testing several hundred cases. Active serum from every case was also sent to Dr. Noguchi of the Rockefeller Institute, who employed his own antihuman system in determining the reaction. The final results obtained by the two methods were approximately the same with the exception of Case 3, in which the Noguchi method showed a negative result on the fiftieth day, while the Wassermann method continued to show a positive reaction at the time of writing. In five of the cases (1, 6, 7, 11, 12) the reaction has become entirely negative at the end of eighty-five, forty-six, seventy, thirty-three and fifty-four days respectively. In one case it became weakly positive with the Wassermann method (negative with Noguchi) at the end of a month and again changed to a strongly positive reaction coincident with a bad relapse of the clinical manifestations.

In observing the general action of salvarsan we were impressed by the remarkable tonic effect of the drug in a number of our patients. From three to five days after treatment a decided improvement in appetite, color and general appearance was noted, especially in Cases 1, 2, 7. In Case 13, however, in which the result of the injection was most favorable, the general condition of the patient seemed decidedly worse for about two weeks after treatment.

In all of the cases a rise of temperature occurred during the first few days after the injection. As a rule, it appeared at the end of twenty-four hours and continued for two or three days with morning remissions. The highest temperature recorded was 102.6 F.; while in the majority of cases it did not exceed 101. In one case the temperature curve was of an intermittent character. In no case was it accompanied by chills. In the case of leprosy the temperature rose to normal, having been subnormal for several weeks previous to the injection.

TABLE 1.—RESULT OF EXAMINATIONS FOR SPIROCHÆTA PALLIDA

While the general febrile symptoms were slight and the cause of little or no disturbance to the patient, the same cannot be said of the local effects of treatment. In almost every case there was considerable pain for the first twenty-four hours following the injections, and as a rule the use of morphin became necessary. In a few cases it was very intense and lasted for about three days. The insoluble injections in the subcutaneous tissue appeared to be more painful than those given in solution in the gluteal muscles. In spite of the unavoidable pain, two of the patients cheerfully submitted to a second injection when relapses occurred.

The induration following the insoluble injections varied considerably in the different cases. It was generally well marked for the first week. In no case has it absolutely disappeared at the time of writing. In three cases (3, 5, 6) it was very severe, accompanied by redness and was the cause of considerable discomfort for about two weeks. No abscesses occurred, although in one case (6) there was a slight necrosis of tissue, followed by a serosanguinolent discharge for three weeks. The induration resulting from the soluble injections in

---

[1] In four of the cases (1, 3, 7, 9) the insoluble injections were given according to the method of Wechselmann. This consisted in grinding up the salvarsan in a mortar with 2 c.c. of a 10 per cent. solution of sodium hydroxid. Glacial acetic acid was then added, drop by drop, until precipitation occurred, after which 2 c.c. of sterile water were added. The mixture was then made neutral [illegible] litmus by the further addition of either 2 per cent. acetic acid [illegible] sodium hydroxid, according to necessity. When completely [illegible] the suspension was centrifuged, the supernatant fluid pipetted off, the residue mixed with 10 c.c. of physiologic [illegible] on and thoroughly shaken. It was then ready for sub[illegible] jection. In six of the cases (2, 4, 5, 6, 8, 10) a neutral [illegible] was made by simply grinding up the salvarsan in a [illegible] h a 10 per cent. solution of sodium hydroxid. The latter [illegible] s added in the proportion of 1.33 c.c. for each decigram [illegible] the mixture being brought up to 10 c.c. in volume by [illegible] f physiologic salt solution. The salvarsan was pre[illegible] soluble injections as follows: The drug was added [illegible] t sterile water in a graduated glass cylinder con[illegible] glass beads, and dissolved at once on shaking. Two [illegible] mal sodium hydroxid solution were then added, causing [illegible] cipitation of the salvarsan, which was redissolved by the further addition, drop by drop, of the sodium hydroxid solution. The mixture was brought up to 20 c.c. in volume by the addition of sterile water and an intramuscular injection of 10 c.c. given in [illegible] h buttock.

TABLE 2.—RESULTS OF TWENTY INJECTIONS OF SALVARSAN

Case No., Sex, Age and Stage	Lesions	Duration of Lesions	Previous Treatment	Date, Dosage and Method of Injection	Local Effect of Injection	Wassermann Reaction	Result of Treatment
1—F.—47— II	Papular syphilid	5 weeks.	None	10/13/10.—Gm. 0.5 in suspension.	Pain rather severe for 12 hours; induration moderate.	Negative at end of 85 days.	Eruption almost disappeared at end of three months; improvement in general health one week after injection.
2—M.—19— II	Pustulo crustaceous syphilid of nose, ear, arms and legs.	8 months.	Continuous Hg. treatment by mouth eight months; grew worse under treatment.	10/15/10.—Gm. 0.4 in suspension.	Pain moderate, lasting 12 hours; induration slight.	Weakly positive end of month; then became strongly positive.	Marked improvement for three weeks, when relapse occurred. (See text.)
3—F.—32—III	Tuberculo-ulcerative syphilid of face.	2 years.	Hg. at irregular intervals by mouth and injection for two years; disease not controlled.	10/22/10.—Gm. 0.5 in suspension.	Pain severe; induration, redness and tenderness marked; slightly red end 2½ months.	Positive at end of 87 days.	Improvement began on second day; nasal discharge stopped at end of one week; crusted and ulcerated lesions healed in ten weeks.
4—F.—20— II	Chancre of lip; macular syphilid; mucous patches.	Eruption 6 days.	None	10/22/10.—Gm. 0.45 in suspension.	Pain and induration moderate and well borne.	Positive at end of 73 days; reaction weaker than at beginning.	Chancre healed in 3 weeks; eruption disappeared at end of 4 weeks; mucous patches healed in 4 days; severe relapse 6½ weeks from time of injection, consisting of mucous patches of mouth and vulva and macular and miliary papular syphilid.
5—F.—27—III	Gumma of clavicle; tubercular syphilid of lip.	Gumma 4 months; lip lesion 12 years.	Hg. at irregular intervals for many years; improved but never cured.	10/22/10.—Gm. 0.45 in suspension.	Pain moderate; induration and redness very marked at first; persisted 2 months.	Positive at end of 80 days.	Gumma nearly cured end one month (see text); lip lesion disappeared in ten days.
6—M.—32— II	Papulo-squamous syphilid; extensive mucous patches.	3 months.	Hg. by mouth for one month.	10/28/10.—Gm. 0.5 in suspension.	Pain and induration marked & persistent; slight tissue necrosis.	Negative at end of 46 days.	Disappearance of mucous patches in ten days; eruption disappeared end of 2½ months.
7—F.—20— II	Papular syphilid	3 weeks.	None	10/28/10.—Gm. 0.4 in suspension.	Pain and induration slight.	Negative at end of 70 days.	Marked improvement in general health at end of five days; gained 10 lbs. in weight since injection; eruption practically disappeared.
8—M.—37— II	Pustular syphilid	4 months.	Hg. by mouth for four months without effect on eruption.	10/29/10.—Gm. 0.5 in suspension.	Pain severe; induration slight.	Negative before and during entire treatment.	Moderate improvement at end of one week; patient failed to return to hospital.
9—M.—21— II	Maculo-papular syphilid	5 weeks.	None	10/29/10.—Gm. 0.45 in susp.	Pain severe first 12 hrs.; induration moderate.	Positive at end of 16 days.	Slight improvement during three weeks, when patient failed to return to hospital.
10—M.—34—III	Tuberculo-ulcerative syphilid of arm, shoulder and abdomen; ulceration of palate	4 months.	Hg. by mouth 2 weeks	11/3/10.—Gm. 0.5 in suspension.	Pain severe second day; induration slight.	Positive at end of 3 weeks.	Lesion healed in three weeks.
11—M.—38—III	Gummatous ulceration of hard and soft palate and ear.	6 months.	Hg by mouth, inunctions and injections, irregularly one year; Hg. very badly borne.	11/10/10.—Gm. 0.5 in solution.	Pain severe for 12 hours; induration lasted 3 weeks.	Negative during entire treatment. (See text).	Astonishing improvement at first; ulceration of palate reduced to half its size at end of one week; marked improvement in general health and appearance; lesions practically healed in 12 days, when relapse occurred. (See text.)
12—M—24— II	Mucous patches; laryngitis.	10 months.	None	11/10/10.—Gm. 0.45 in solution.	Severe pain; marked induration of buttocks 2 weeks.	Negative end of 54 days.	Mucous patches disappeared three days after injection; hoarseness began to improve on second day, and by fifth day voice was normal.
13—F.—46—III	Tuberculo-crustaceous serpiginous syphilid.	1 year.	None	11/15/10.—Gm. 0.5 in solution.	Severe pain for 2 days; marked induration of buttocks 3 weeks.	Weakly positive at end of 63 days.	Eruption almost disappeared at end of three weeks; entirely well at end of one month; general condition worse for two weeks as result of treatment, anemia, loss of appetite and weight.
14—F.—35—III	Gumma of soft palate and pharynx; gummatous infiltration of access. sinuses; deafness.	3 years.	Hg. and KI by mouth irregularly one year.	12/3/10.—Gm. 0.45 in solution.	Pain and induration moderate.	Positive at end of 46 days.	Gumma nearly healed at end of six weeks.
15—M.—43—III	Tuberculo-ulcerative syphilid of thigh.	7 months.	None	12/5/10.—Gm. 0.45 in solution.	Pain severe 6 days; induration marked and lasted 3 weeks.	Strongly positive at end of 43 days.	Lesions entirely healed at end of 3½ weeks.
16—M.—38—III	See Case 11. Second injection.	....	....	12/15/10.—Gm. 0.6 in solution.	Practically no pain or induration.	Continued to be negative.	Improvement of ulceration marked at end of first week; process then remained about stationary and relapsed slightly at end of third week.
17—M.—19— II	See Case 2. Second injection.	....	....	12/22/10.—Gm. 0.45 in sol.	Pain and induration slight.	Positive at end of 26 days.	Continued slow improvement for a month.
18—M.—	lar leprosy	6 years.	Chaulmoogra oil, strychnin and mercury.	1/5/11.—Gm. 0.4 in solution.	Pain severe; induration severe.	No examination made after treatment.	Absolutely no effect on lesions; since treatment has been confined to bed, his general condition having become markedly worse.
19—F.—	lceration	6 months.	None	1/12/11.—Gm. 0.6 in solution.	Pain severe; induration moderate.	Positive at end of 1 week.	Marked improvement in lesions at end of a week.
20—F.	...	9 months.	Practically none	1/12/11.—Gm. 0.6 in solution.	Pain 24 hours; no induration.	Positive at end of 1 week.	Improvement at end of one week.

EXPERIENCE WITH SALVARSAN

EHRLICH-HATA'S 606 IN THE NEW YORK SKIN AND CANCER HOSPITAL

HOWARD FOX, M.D., and WILLIAM B. TRIMBLE, M.D.
NEW YORK

Through the kindness of Dr. Flexner of the Rockefeller Institute we received in October twenty tubes of Ehrlich's 606 for experimental use in the Skin and Cancer Hospital. The twenty tubes have been used for the treatment of eighteen patients, a second injection having been given in two of the cases in which relapses occurred. All of the patients remained in bed at least three days after treatment and then continued under observation at the hospital or returned to the dispensary at weekly intervals. All except two of the patients have remained under observation up to the present time.

With the exception of a patient with nodular leprosy to whom the new remedy was experimentally given, the patients selected for treatment were those who presented active syphilitic manifestations and (except in Case 8) a positive Wassermann reaction. The choice of patients was limited to those in whom ophthalmoscopic examination of the fundus and examination of the heart and urine showed no deviation from the normal condition.

The injections[1] of salvarsan were given either in suspension or in solution in doses varying from 40 to 60 centigrams. In the first nine cases the drug was given in a neutral suspension in the subcutaneous tissue of the interscapular region. In one case (10) the injection was made in the quadratus lumborum muscle. In the last ten cases, soluble injections were given in the gluteal muscles, according to the method of Lesser.

Examinations for *Spirochæta pallida* were made with the dark-field illuminator in five of the cases and showed a rapid disappearance of the organisms after injection. In no case could any spirochetes be found at the end of seventy-two hours after treatment, as seen in Table 1.

The Wassermann reaction was performed in every case before the injection was given and was afterward repeated at weekly or somewhat less frequent intervals. It was found to be positive in all except one case (9) in which mercury had been previously administered for several months. The original Wassermann method was performed by us, using two antigens for every case, one of the antigens being an alcoholic extract of syphilitic liver that had been found reliable in testing several hundred cases. Active serum from every case was also sent to Dr. Noguchi of the Rockefeller Institute, who employed his own antihuman system in determining the reaction. The final results obtained by the two methods were approximately the same with the exception of Case 3, in which the Noguchi method showed a negative result on the fiftieth day, while the Wassermann method continued to show a positive reaction at the time of writing. In five of the cases (1, 6, 7, 11, 12) the reaction has become entirely negative at the end of eighty-five, forty-six, seventy, thirty-three and fifty-four days respectively. In one case it became weakly positive with the Wassermann method (negative with Noguchi) at the end of a month and again changed to a strongly positive reaction coincident with a bad relapse of the clinical manifestations.

In observing the general action of salvarsan we were impressed by the remarkable tonic effect of the drug in a number of our patients. From three to five days after treatment a decided improvement in appetite, color and general appearance was noted, especially in Cases 1, 2, 7. In Case 13, however, in which the result of the injection was most favorable, the general condition of the patient seemed decidedly worse for about two weeks after treatment.

In all of the cases a rise of temperature occurred during the first few days after the injection. As a rule, it appeared at the end of twenty-four hours and continued for two or three days with morning remissions. The highest temperature recorded was 102.6 F.: while in the majority of cases it did not exceed 101. In one case the temperature curve was of an intermittent character. In no case was it accompanied by chills. In the case of leprosy the temperature rose to normal, having been subnormal for several weeks previous to the injection.

TABLE 1.—RESULT OF EXAMINATIONS FOR SPIROCHÆTA PALLIDA

Case No.	Lesions Examined	Spirochetes Present Before Treatment	End 24 Hours	Hours 48	72 Hours

2	Ulcers...	Few.......	Few.......	None.....	....
5	Chancre..	Large numbers.	Moderate numbers.	Few......	None.....
8	Papules..	Moderate numbers.	Few.......	None.....	....
13	Mucous patches	Enormous numbers.	Moderate numbers.	None.....	....

While the general febrile symptoms were slight and the cause of little or no disturbance to the patient, the same cannot be said of the local effects of treatment. In almost every case there was considerable pain for the first twenty-four hours following the injections, and as a rule the use of morphin became necessary. In a few cases it was very intense and lasted for about three days. The insoluble injections in the subcutaneous tissue appeared to be more painful than those given in solution in the gluteal muscles. In spite of the unavoidable pain, two of the patients cheerfully submitted to a second injection when relapses occurred.

The induration following the insoluble injections varied considerably in the different cases. It was generally well marked for the first week. In no case has it absolutely disappeared at the time of writing. In three cases (3, 5, 6) it was very severe, accompanied by redness and was the cause of considerable discomfort for about two weeks. No abscesses occurred, although in one case (6) there was a slight necrosis of tissue, followed by a serosanguinolent discharge for three weeks. The induration resulting from the soluble injections in

---

[1] In four of the cases (1, 3, 7, 9) the insoluble injections were given according to the method of Wechselmann. This consisted in grinding up the salvarsan in a mortar with 2 c.c. of a 10 per cent. solution of sodium hydroxid. Glacial acetic acid was then added, drop by drop, until precipitation occurred, after which 2 c.c. of sterile water were added. The mixture was then made neutral [illegible] litmus by the further addition of either 2 per cent. acetic acid [illegible] sodium hydroxid, according to necessity. When completely [illegible] the suspension was centrifuged, the supernatant fluid [illegible] pipetted off, the residue mixed with 10 c.c. of physiologic [illegible]on and thoroughly shaken. It was then ready for sub[illegible]jection. In six of the cases (2, 4, 5, 6, 8, 10) a neutral [illegible] was made by simply grinding up the salvarsan in a [illegible] a 10 per cent. solution of sodium hydroxid. The latter [illegible]s added in the proportion of 1.33 c.c. for each decigram [illegible] the mixture being brought up to 10 c.c. in volume by [illegible]f physiologic salt solution. The salvarsan was pre[illegible]soluble injections as follows: The drug was added [illegible]t sterile water in a graduated glass cylinder con[illegible]glass beads, and dissolved at once on shaking. Two [illegible]mal sodium hydroxid solution were then added, causing [illegible]pitation of the salvarsan, which was redissolved by the [illegible]rther addition, drop by drop, of the sodium hydroxid solution. The mixture was brought up to 20 c.c. in volume by the addition of sterile water and an intramuscular injection of 10 c.c. given in each buttock.

TABLE 2.—RESULTS OF TWENTY INJECTIONS OF SALVARSAN

Case No., Sex, Age and Stage	Lesions	Duration of Lesions	Previous Treatment	Date, Dosage and Method of Injection	Local Effect of Injection	Wassermann Reaction	Result of Treatment
1—F.—47— II	Papular syphilid	5 weeks.	None	10/13/10.—Gm. 0.5 in suspension.	Pain rather severe for 12 hours; induration moderate.	Negative at end of 85 days.	Eruption almost disappeared at end of three months; improvement in general health one week after injection.
2—M.—19— II	Pustulo crustaceous syphilid of nose, ear, arms and legs.	8 months.	Continuous Hg. treatment by mouth eight months; grew worse under treatment.	10/15/10.—Gm. 0.4 in suspension.	Pain moderate, lasting 12 hours; induration slight.	Weakly positive end of month; then became strongly positive.	Marked improvement for three weeks, when relapse occurred. (See text.)
3—F.—32—III	Tuberculo-ulcerative syphilid of face.	2 years.	Hg. at irregular intervals by mouth and injection for two years; disease not controlled.	10/22/10.—Gm. 0.5 in suspension.	Pain severe; induration, redness and tenderness marked; slightly red end 2½ months.	Positive at end of 87 days.	Improvement began on second day; nasal discharge stopped at end of one week; crusted and ulcerated lesions healed in ten weeks.
4—F.—20— II	Chancre of lip; macular syphilid; mucous patches.	Eruption 6 days.	None	10/22/10.—Gm. 0.45 in suspension.	Pain and induration moderate and well borne.	Positive at end of 73 days; reaction weaker than at beginning.	Chancre healed in 3 weeks; eruption disappeared at end of 4 weeks; mucous patches healed in 4 days; severe relapse 6½ weeks from time of injection, consisting of mucous patches of mouth and vulva and macular and miliary papular syphilid.
5—F.—27—III	Gumma of clavicle; tubercular syphilid of lip.	Gumma 4 months; lip lesion 12 years.	Hg. at irregular intervals for many years; improved but never cured.	10/22/10.—Gm. 0.45 in suspension.	Pain moderate; induration and redness very marked at first; persisted 2 months.	Positive at end of 80 days.	Gumma nearly cured end one month (see text); lip lesion disappeared in ten days.
6—M.—32— II	Papulo-squamous syphilid; extensive mucous patches.	3 months.	Hg. by mouth for one month.	10/28/10.—Gm. 0.5 in suspension.	Pain and induration marked & persistent; slight tissue necrosis.	Negative at end of 46 days.	Disappearance of mucous patches in ten days; eruption disappeared end of 2½ months.
7—F.—20— II	Papular syphilid	3 weeks.	None	10/28/10.—Gm. 0.4 in suspension.	Pain and induration slight.	Negative at end of 70 days.	Marked improvement in general health at end of five days; gained 10 lbs. in weight since injection; eruption practically disappeared.
8—M.—37— II	Pustular syphilid	4 months.	Hg. by mouth for four months without effect on eruption.	10/29/10.—Gm. 0.5 in suspension.	Pain severe; induration slight.	Negative before and during entire treatment.	Moderate improvement at end of one week; patient failed to return to hospital.
9—M.—21— II	Maculo-papular syphilid	5 weeks.	None	10/29/10.—Gm. 0.45 in susp.	Pain severe first 12 hrs.; induration moderate.	Positive at end of 16 days.	Slight improvement during three weeks, when patient failed to return to hospital.
10—M.—34—III	Tuberculo-ulcerative syphilid of arm, shoulder and abdomen; ulceration of palate	4 months.	Hg. by mouth 2 weeks	11/3/10.—Gm. 0.5 in suspension.	Pain severe second day; induration slight.	Positive at end of 3 weeks.	Lesion healed in three weeks.
11—M.—38—III	Gummatous ulceration of hard and soft palate and ear.	6 months.	Hg. by mouth, inunctions and injections, irregularly one year; Hg. very badly borne.	11/10/10.—Gm. 0.5 in solution.	Pain severe for 12 hours; induration lasted 3 weeks.	Negative during entire treatment. (See text).	Astonishing improvement at first; ulceration of palate reduced to half its size at end of one week; marked improvement in general health and appearance; lesions practically healed in 12 days, when relapse occurred. (See text.)
12—M—24— II	Mucous patches; laryngitis.	10 months.	None	11/10/10.—Gm. 0.45 in solution.	Severe pain; marked induration of buttocks 2 weeks.	Negative end of 54 days.	Mucous patches disappeared three days after injection; hoarseness began to improve on second day, and by fifth day voice was normal.
13—F.—46—III	Tuberculo-crustaceous serpiginous syphilid.	1 year.	None	11/15/10.—Gm. 0.5 in solution.	Severe pain for 2 days; marked induration of buttocks 3 weeks.	Weakly positive at end of 63 days.	Eruption almost disappeared at end of three weeks; entirely well at end of one month; general condition worse for two weeks as result of treatment, anemia, loss of appetite and weight.
14—F.—35—III	Gumma of soft palate and pharynx; gummatous infiltration of access. sinuses; deafness.	3 years.	Hg and KI by mouth irregularly one year.	12/3/10.—Gm. 0.45 in solution.	Pain and induration moderate.	Positive at end of 46 days.	Gumma nearly healed at end of six weeks.
15—M.—43—III	Tuberculo-ulcerative syphilid of thigh.	7 months.	None	12/5/10.—Gm. 0.45 in solution.	Pain severe 6 days; induration marked and lasted 3 weeks.	Strongly positive at end of 43 days.	Lesions entirely healed at end of 3½ weeks.
16—M.—38—III	See Case 11. Second injection.	....	....	12/15/10.—Gm. 0.6 in solution.	Practically no pain or induration.	Continued to be negative.	Improvement of ulceration marked at end of first week; process then remained about stationary and relapsed slightly at end of third week.
17—M.—19	See Case 2. Second injection.	....	....	12/22/10.—Gm. 0.45 in sol.	Pain and induration slight.	Positive at end of 26 days.	Continued slow improvement for a month.
18—M.—	ular leprosy	6 years.	Chaulmoogra oil, strychnin and mercury.	1/5/11.—Gm. 0.4 in solution.	Pain severe; induration severe.	No examination made after treatment.	Absolutely no effect on lesions; since treatment has been confined to bed, his general condition having become markedly worse.
19—F.	ulceration	6 months.	None	1/12/11.—Gm. 0.6 in solution.	Pain severe; induration moderate.	Positive at end of 1 week.	Marked improvement in lesions at end of a week.
20—F	...	9 months.	Practically none	1/12/11.—Gm. 0.6 in solution.	Pain 24 hours; no induration.	Positive at end of 1 week.	Improvement at end of one week.

the buttocks was extremely variable in the different cases. It was greatest, as a rule, on the third day after treatment. In some of the cases it was slight and occasioned very little inconvenience. Two of the patients, however, complained of considerable lameness for about two weeks. While the pain and induration were by no means unbearable they were severe enough to make it very desirable to continue our experiments with other methods of injection, concerning which we hope to report in a later communication.

The result of the twenty injections from a clinical standpoint were in some respects encouraging, in other disappointing. The most brilliant symptomatic result was obtained in Case 13, in which a superficial tuberculo-crustaceous syphilid disappeared at the end of a month. Even in this case it is not impossible that a single injection of calomel or one or two injections of salicylate of mercury might not have accomplished the same results. An excellent result was also obtained in Case 5, in which a mild tubercular syphilid of the lip that had existed for twelve years (according to the patient's statement) disappeared at the end of ten days. A gumma at the sternoclavicular point occurring in the same patient was also healed at the end of a month. In three of the cases (1, 6, 7) presenting early papular syphilids, the results were apparently not so good as those that might have been obtained from mercury. The lesions, however, finally disappeared in each case, and the Wassermann reaction became negative.

In three tuberculo-ulcerative cases (3, 10, 15) and in a case of gumma of the pharynx and palate (14), the results were satisfactory from a clinical standpoint, although the Wassermann reaction has not as yet become negative. The result of treatment in Case 3 was especially gratifying, as it had been very difficult to control the disease with mercury. In three cases in which mucous patches were present (4, 6, 12) there was a most rapid disappearance of the lesions after injection. The result of treatment in the case of leprosy was most unsatisfactory. No change whatever occurred in the lesions and the patient's general condition has become decidedly worse.

Relapses occurred in three cases, in two of which we thought at first that splendid results had been obtained. One of these cases (2) presented a pustulo-crustaceous syphilid of somewhat malignant type that had grown worse under internal administration of mercury. The patient improved rapidly for a month, the Wassermann reaction becoming nearly negative and the ulcerated lesions of the nose, ear, arms and legs healing almost completely. He then suffered a severe relapse, his condition becoming nearly as bad as at the outset. He was given a second injection and the manifestations have again almost disappeared.

A disappointing relapse was also shown by a patient (Case 11) with extensive gummatous ulceration of the [illegible]rd and soft palate. The improvement was most striking [illegible] first, the ulcerated area being reduced to half its size at the end of a week. A relapse then [illegible] and the patient was given a second injection [illegible]s again followed by a relapse. As it is almost [illegible] to administer mercury to this patient it is our [illegible] give him one or two more injections of sal[illegible] near future.

[illegible] unwarranted to draw any general conclusions from our limited material. It must be [illegible]mitted, however, that the effect of the new remedy, in causing lesions to disappear rapidly, has been striking in several of our cases. In other cases, however, the lesions have disappeared rather slowly. In comparison with what might have been expected from a vigorous mercurial treatment, the results do not appear to be especially brilliant. In several of the cases the disease had not been controlled by mercury and responded very favorably to salvarsan. Indeed in one case (11) [illegible] patient had found it practically impossible to take mercury in spite of persistent attempts to administer the drug by mouth, inunctions and injections.

In the limited number of cases in which we have used salvarsan it has seemed to us that the lesions of the mucous membranes have yielded more quickly than those of the cutaneous surface. As has been said, the brilliant results in some cases have been only temporary and the relapses that have occurred have followed the improvement with discouraging rapidity. Our results are favorable enough to make us willing to continue our experiments with salvarsan in a larger and more varied number of cases than the ones that are here reported.

In conclusion we wish to thank Dr. George Henry Fox for much of the material and for the privilege of treating the cases at the Skin and Cancer Hospital; to Dr. Udo J. Wile for the spirochete examinations, and to Dr. Robert G. Reese for the ophthalmoscopic examinations.

616 Madison Avenue; 30 East Twenty-Eighth Street.

GENERAL CHEMICAL ASPECT OF INTERNAL SECRETION

RUSSELL H. CHITTENDEN, Ph.D.
NEW HAVEN, CONN.

Anyone who has watched the recent development of knowledge concerning the internal secretions cannot help being impressed with the significance of the results in their bearing on the chemical processes of the body. Not only have we learned that certain of the ductless glands, which hitherto were considered of little importance for the welfare of the organism, manufacture specific internal secretions all-powerful for the maintenance of health, but it has also been shown that these secretions owe their power to definite chemical substances, produced through the metabolic activity of the gland cells. The ductless glands become, then, miniature laboratories charged with the function of elaborating specific chemical products which are needed for maintaining the normal rhythm of nutrition. Let these glands cease their functional activity and the lack of their specific products entails disease and possible death. On the other hand, increased activity may be attended with equally disturbing results.

THE ADRENALS

A study of the product formed in the adrenals, for example, shows us that we have here a powerful substance, which in undue amount acts as a violent poison (0.2 mg. per kilo of body weight being a lethal dose for rabbits when given by intravenous injection), and in smaller amount exerts a striking influence on blood-pressure. This blood-pressure-raising constituent of the adrenals is a well-defined chemical substance, crystalline, basic in character and readily prone to undergo oxidation. Chemically it is a ketone-like body, having the structure of methylaminoacetopyrocatechol, and it is now made synthetically. To-day we fully recognize that the unique action of the internal secretion from this particular gland is due mainly, if not solely, to epinephrin, which fulfils a specific function both in health and in disease. Further, the marked vasoconstrictor action of this substance has led to its widespread use as a therapeutic agent, so that we now have the natural base and the synthetic product available for use in the treatment of diseased conditions. We understand, further, that the marked and sudden rise in blood-pressure that attends the introduction of epinephrin[1] is due to two causes, viz.. an accelerated and more energetic heart's action, together with a contraction of the smaller arteries and arterioles, especially those of the skin and in the region of the splanchnics. Section of the nerves is without visible effect on the blood volume, thereby indicating that epinephrin acts directly on the periphery, on the blood-vessels themselves.

Especially significant are the observations recorded bearing on a comparison of the natural base and the synthetic product, sometimes termed "suprarenin." The epinephrin prepared from the gland substance is optically active with a specific rotation of —51°. In other words, *it is a levo-rotary body. The synthetic base, on* the other hand, is optically inactive. Moreover, it has been demonstrated that the latter body has a far less powerful physiologic action than the natural base. Cushny, from his experiments, has concluded that natural epinephrin acts twice as strongly on blood-pressure as the synthetic or racemic epinephrin, and presumably also on the other organs affected by this substance. From this, the assumption is fair that dextro-epinephrin is without action as a vaso-constrictor. Finally, Flächer[2] has succeeded in splitting the optically inactive, synthetic epinephrin into its two optically active halves, and finds that the synthetic dextro-epinephrin and the natural dextro-epinephrin are physiologically identical.

Broadly speaking, the important point to be emphasized here is that the animal body in its special laboratory, the cell, follows a well-defined line of action producing compounds that are optically active; compounds in which the asymmetric carbon atom is conspicuous. The illustration of epinephrin is in harmony with many of the metabolic processes of the body in which an asymmetric carbon atom is a determining factor in the physiologic character of the substance. Nature makes use of optically active products, while the corresponding products turned out by the hand of man, though identical structurally, exhibit differences in steroisomerism.

The internal secretion from the adrenals may be taken as illustrating a form of chemical control, by means of which many of the processes of the body are capable of being modified. Variations in blood-volume and blood-pressure are conspicuous causes of modification in glandular activity, and we may well conjecture that variations in the amount of epinephrin produced and thrown into the blood-current may be responsible for many quantitative changes in function. Aside from this, we see in the marked glycosuria produced by epinephrin an illustration of specific action, the significance of which cannot be overlooked. Subcutaneous administration of epinephrin is followed by the appearance of dextrose in the urine, coupled with a true condition of hyperglycemia. As Elliott[3] has pointed out, the striking characteristic of ephinephrin is its tendency to stimulate plain muscle and gland cells that are or have been in functional union with sympathetic nerve fibers. In harmony with this fact, Underhill and Closson[4] suggest that the glycosuria produced by epinephrin is due to a stimulation of the sympathetic nerves leading to the liver or to other storehouses of carbohydrate, causing these organs to throw out their stored-up material in the form of dextrose. At the same time there may be a diminished storage of dextrose owing to stimulation of the hepatic cells by the epinephrin, thus causing these cells to reject the dextrose brought to them. However this may be, small quantities of epinephrin injected lead to a marked glycosuria, and apparently by an action on the nervous system through the intermediation of the sympathetic.

We thus have suggested the picture of a miniature gland endowed with the function of producing a powerful chemical substance which may serve to control and modify many of the processes of the body. Its importance to the organism is fully apparent from the results that fol*low complete extirpation of the adrenals, while its phys*iologic strength is equally manifest from the effects of subcutaneous injections of epinephrin.

THYROIDS AND PARATHYROIDS

Equally striking are the data that can be presented in connection with the thyroids and parathyroids. Ignoring all matters of detail, there stands out prominently one fundamental fact that in these tissues there is produced a peculiar chemical complex—characterized by containing iodin—known as iodothyrin. The chemical nature of this substance is not as fully understood as that of epinephrin, but it is apparently a cleavage product of a still larger protein complex. However this may be, the active principle is endowed with marked physiologic power. Extirpation of the thyroid tissues is followed by profound changes leading to myxedema, tetany, retardation of skeletal growth, etc., conditions which can be prevented or obviated in greater or less degree by administration of thyroidal tissue. Similarly, diseases which are associated with functional disturbance of the thyroids can be made to show great improvement by feeding sheep's thyroids or by administering iodothyrin. There are many interesting facts that might be cited regarding the relative significance of the thyroids and parathyroids, but the point to be emphasized here is that the thyroidal tissues manufacture one or more specific chemical substances which are essential for normal growth and development; substances which either directly or indirectly control certain nutritive processes on which good health and life itself depends.

Physiologic experiment shows us that iodothyrin fed to healthy animals tends to accelerate in small degree nitrogen metabolism. It likewise causes an increased excretion of phosphorus as phosphoric acid through the urine and also appears to stimulate the combustion of fatty material. There is thus apparent a certain ground
for the assumption that normally the thyroid gl[illegible] could
essential factors in the regulation of body m[illegible]t ensued,
Further, experiments seem to show that if all
tissue is removed from a healthy animal there [illegible] F. The

words of Professor Schäfer,[5] "a 'colloid' material which contains active principles or hormones acting on the heart, blood-vessels and kidneys. Probably there are several such hormones acting on the blood-vessels and kidneys independently, and also acting antagonistically; so that according to circumstances either a rise or a fall of blood-pressure, an increased or a diminished secretion of urine may be produced, and the effects on the kidneys may be independent of those on the blood-vessels."

CORRELATION OF INTERNAL SECRETIONS

These brief statements and suggestions may be taken as emphasizing the specific action of definite chemical substances which constitute the basis of certain internal secretions. It is becoming apparent, further, that these ductless glands in their physiologic activity also exercise a regulating action on each other; that they are in some manner correlated. Clinicians have frequently called attention to the fact that a disturbance or impairment of function of one ductless gland quite commonly leads to a disturbance in the functional activity of some other ductless gland. Evidence at present available, for example, tends to indicate that the pancreas and the thyroid mutually retard the action of each other. The same is believed to be true of the pancreas and the chromaffin system, while the thyroid and the chromaffin system mutually increase the action of one another.[6] As to the explanation of these phenomena we can at present only conjecture, but there is a strong suggestion that chemical reactions are involved here, the full meaning of which can hardly be hoped for until we know more concerning the chemical composition of the secretion concerned.

My object, however, in referring to these unsettled questions is merely to emphasize the many ways in which these internal secretions probably act in the body, and the consequent importance of the chemical regulation they exercise in controlling metabolic processes. But it is to be remembered that in touching on the ductless glands we are only at the threshold of the subject. The pioneer work of Baumann in 1895 with the thyroid gland, accompanied by the discovery of iodothyrin, led to a fuller realization of the significance of internal secretion in general. Physiologists soon came to appreciate the far-reaching influence of the continual exchange of matter between all the living cells of the organism and the surrounding blood, lymph and tissue juices. In other words, there has come about a fuller realization of the fact that, broadly speaking, internal secretions may be considered as common to every group of specialized cells and that their chemical nature and physiologic action merit consideration. The ductless glands serve to illustrate special forms of internal secretion, the active substances of which are of the utmost importance to the organism. To-day, however, we recognize that the cells of every organ and tissue of the body are continually forming intermediate products [illegible]nd-products, which are absorbed by blood and [illegible] and which may serve as stimulants to other tissue [illegible] in some manner exercise an influence on the [illegible] processes of other organs or tissues. These [illegible]nternal secretion are, many of them at least, [illegible]rtance, and merit as much consideration as [illegible] that originate in the ductless glands. [illegible] mind, lies the fundamental point to be [illegible]zed in considering the chemical aspects of internal secretion. Chemical correlation, chemical control, stand out with startling distinctness, and this in a general way is equally true of every active gland and tissue of the body. It is as true of a gland like the pancreas, which has for one of its functions the manufacture of a specific digestive fluid, as it is of the thyroid, which apparently produces only an internal secretion. Even the excretory organs, like the kidneys, which seemingly are concerned solely in draining from the blood certain so-called waste-products, are plainly susceptible to the physiologic action of some of the substances they elaborate; the epithelial cells of the glomeruli and tubuli, for example, being noticeably sensitive to the action of purins, uric acid, etc.

Look also at the process of respiration, in which the waste product carbon dioxid, resulting from the metabolism of every tisssue cell, acts as a stimulant to the mechanism in the central nervous system, by which regulation of the respiratory movements is accomplished. Equally suggestive, though more specific in character, are the other "hormones" so thoroughly studied by Bayliss and Starling, emphasizing as they do the important part played by many internal secretions emanating from particular groups of cells in starting or controlling processes taking place in other glands or tissues. In the secretion of the pancreatic juice, the hypothetic nerve-control so long sought for gives place to a chemical control through the prosecretin manufactured in the epithelial cells of the upper part of the intestine. This substance, under the influence of the hydrochloric acid of the gastric juice, undergoes conversion into secretin, and then brought to the pancreas by the blood sets up a voluminous secretion of pancreatic juice. Again, in the intestine we find a specific substance elaborated, enterokinase, which, reacting with the trypsinogen of the pancreatic secretion, converts it into an active proteolytic enzyme. In the mammary gland we have another equally striking suggestion of chemical stimulation resulting from a substance or substances produced in a remote structure, by which the process of lactation is made possible. As the experiments of Claypon and Starling[7] indicate, the growth of the mammary glands during pregnancy is apparently due to the action of a specific chemical stimulus which has its origin in the fertilized ovum. The amount of this substance increases with the growth of the fetus and is therefore largest during the latter half of pregnancy. Lactation is supposed to be due to the removal of this particular substance, or hormone, which is therefore to be regarded as exerting an inhibitory influence on the mammary gland cells, hindering their secretory activity and furthering their growth. To quote more fully from Claypon and Starling:

> During sexual life, therefore, the ovaries are continually producing a substance which exerts an influence on both glands and uterus. With the occurrence of conception there is at once a great growth of what we may call germinal material. With the growth of the fertilized ovum the amount of hormone produced in the ovum must also increase in proportion. In the early stages of pregnancy the chief source of this hormone may perhaps be located in the chorionic villi, but with the growth of the body of the fetus this latter must take a preponderating share in the preparation of the hormone. We have no reason to suppose that fetal elements of the placenta entirely lose this function of the germinal cells, but the negative results of injection of placentæ in our experiments show that it is impossible to ascribe to the placenta, as is done by Halban, a preponderating part in the preparation of this hormone.

CONCLUSION

Facts such as these, like the data gradually collecting regarding the internal secretions from the ductless glands, emphasize the part which specific chemical products play in the regulation of body metabolism; they serve to call attention to the importance and the general application of the methods of chemical control which the organism makes use of in regulating its affairs. Further, products of tissue metabolism in general, whether classified as intermediate or as end-products, in their passage through the circulation have abundant opportunity to exercise an influence on the activity of other tissues or organs. They are true internal secretions, as much so as the more specific products which are apparently formed for some special purpose, and as such they illustrate the truth of the general hypothesis that the products of all tissue cells are efficacious in greater or less degree as forms of chemical control in the processes of the body.

THE INTERNAL SECRETION OF THE PANCREAS

W. G. MACCALLUM, M.D.
NEW YORK

Ever since the early experiments which culminated in those of von Mering and Minkowski, showing that removal of the pancreas causes the most profound and extraordinary disturbances in the general metabolism, and more especially in the metabolism of carbohydrates, the search for an explanation has been most active. Notwithstanding the fact that the literature on this subject is enormous and that many side-lights have been cast on the problem, it is still impossible for us to say with any certainty just what we have done in extirpating the pancreas to cause all these changes, and the further the matter is studied the more complex seem the possible relations which exist, not only between this organ and the tissues which are especially concerned in the assimilation and metabolism of the foodstuffs of the body, but also the relations which it bears to the nervous system and to other organs or groups of organs which are important to the economy in a somewhat similar way.

The pancreas has a complicated structure and it seems clear that its functions are manifold, for on the one hand by its secretions, which are poured into the intestine, it plays an extremely prominent rôle in the preparation of all classes of food for absorption, while on the other hand there still remain the functions which we can see so obscurely in their relation to general metabolism and which are apparently quite independent of this external or intestinal secretion. The nature of these latter functions must form our subject for discussion to the exclusion of the former.

Nearly everyone in these days of ferments thinks of this influence of the pancreas as being carried out by the aid of some chemical material which is secreted into the blood-stream, and only Pflüger has maintained that there is no such internal secretion, but that the results of extirpation are due to injuries to the nervous system at one point or other. The idea of a chemical internal secretion is suggested and supported by the observations on other organs whose influence over metabolism is great, and for some of which an extract can be obtained which will practically take the place of the organ if it be destroyed. Such direct proof can hardly be brought for the pancreas, but still the evidence which I shall recount is so strong that we can hardly escape from the conclusion that there is an internal secretion even though we may not say exactly how and where it acts.

The simplest case in which we can study the functions of an organ is perhaps that in which these functions are abolished. There are many conditions in which we suspect an insufficiency of the pancreas and many others in which similar symptoms are due to other things, and although these two throw light on the function of the pancreas, it is perhaps best to base our considerations chiefly on the results of extirpation of the gland. This is promptly followed in all animals by the appearance in the circulating blood of an excessive amount of sugar, much of which passes into the urine, causing glycosuria. The organs lose their power to store up glycogen, there is a very great increase in the breaking down of proteins and of fats, the animal becomes emaciated and in some cases, owing probably to the abnormal decomposition of the fat, there appear in the blood and urine various acid substances, beta-oxybutyric and diacetic acids and acetone, which are very poisonous and often cause death in human beings the subject of diabetes by producing the so-called diabetic coma.

All of this is obviated by the presence of the pancreas, and not necessarily the whole pancreas; a portion of it is sufficient to maintain the animal in health, as was shown by Minkowski, who transplanted a part, with its blood-vessels, into the abdominal wall and removed the rest.

This being so, the question at once arises as to what part of the pancreas is responsible for this function and what is the mechanism of its action. I shall pass over here with but brief mention the experiments of Pflüger in which he contends that the separation of the pancreas from the duodenum and the tearing of nerves is responsible for glycosuria, for, as we shall see, much greater injury can be done with no such effect. The whole subject of the relation of the pancreas from an anatomic point of view, and especially of the relation of the islands of Langerhans to glycosuria and diabetes, has been so well reviewed by Sauerbeck that there is but little to add to what he brings forward. Briefly, the dispute hangs on whether the islands of Langerhans alone possess this all-important function or whether the pancreatic glandular substance in general is concerned; and it is well known that basing their opinions on pathologic cases, Opie, Ssobolew and many others hold to the view that the prevention of glycosuria, etc., is a specific function of the islands, while Hansemann, Herxheimer and others find the evidence for this inclusive and maintain that diabetes is due in each case to an inadequate functioning of the whole pancreas. The theory as to the special relation of the islands of Langerhans to diabetes was suggested to Opie by the discovery of a case of diabetes mellitus in which while the pancreas in general was practically normal the great majority [illegible] islands of Langerhans had undergone a hya[illegible] morphosis and were thus thrown out of func[illegible] the other hand, it is possible to ligate the [illegible] ducts and thus to cause the atrophy of all [illegible] the gland without affecting the islands [illegible] which have no connection with the du[illegible] condition no glycosuria results. Even [illegible] results of an experiment which I described [illegible] publication in which a portion of the pancreas [illegible] ligated off from the rest and allowed to undergo atrophy for a year. At the end of that time its place in [illegible] mesentery, marked out by a black ligature, showed only a thin film of opalescent tissue composed practically entirely of islands of Langerhans. At this time the remainder of the pancreas was extirpated and after a transient glycosuria the dog recovered completely and was able to take by mouth nearly 40 gm. of glucose at one dose without showing any glycosuria. The subsequent extirpation of the film of tissue which had been left behind caused the development of the most intense and persistent glycosuria. The inference seems justified that the islands of Langerhans alone are able to maintain carbohydrate metabolism.

Interesting results which bear on the nature of the pancreatic function are brought forward by Forschbach, who produced the condition of parabiosis in two animals. The effect of the extirpation of the pancreas in one was annulled by its connection with the other. Since this was a vascular connection only, nervous influences could be ruled out and the symptoms must have been prevented by some substance passing from one animal to the other. In spite of this apparently conclusive evidence of the existence of some internal secretion of the pancreas we have not been able to demonstrate it satisfactorily by positive methods as in the case of the thyroid, although Zuelzer claims to be able with a deproteinized extract of the pancreas to annul the glycosuria which follows pancreatectomy. Indeed, we are not even informed as to where such a secretion must exert its function.

It has been shown that in most cases after extirpation of the pancreas, the liver and other normal depots are extremely poor in glycogen, and Ivar Bang makes the statement that the function of the internal secretion of the pancreas is to control the storage of sugar in this form—without it there must be an excess of soluble sugar in the blood and consequently glycosuria. A moment's reflection will make clear, however, that this could not in itself explain the phenomena of pancreatic diabetes, for when the pancreas is extirpated in hungering and glycogen-free animals there suddenly appears, without the intake of any carbohydrates, a great excess of circulatory sugar and glycosuria. The disturbance is far deeper than the mere inability to polymerize and store sugar. There is actually a new formation of sugar from proteins and from fats; even the tissues are consumed, and that portion of their molecules which will form sugar is set free as such in the circulating blood. Nor can we find a satisfactory explanation in disturbances in the activity of diastatic ferments which set free the sugar from its polymerized form. It seems quite possible that the pancreas may control this in some way, allowing only so much as is necessary to be turned into the circulation, so that when its influence is lost, mobilization of the sugar is too rapid. In this sense it is actually found (Zuelzer, Falta and others) that the addition of pancreatic extract to adrenalin will prevent the production of glycosuria by that substance, and that the
constipation of the pancreas by pilocarpin will in some

desc[illegible] in the tissues it is oxidized to furnish and energy, but it appears that this oxidation is not easy unless the sugar be first split into somewhat simpler substances, a process which may be spoken of as glycolysis and conceived of as being carried out by a glycolytic ferment. The most earnest efforts have been made to determine the existence of such ferments in the body and if possible to ascertain the relation they bear to the pancreas. The results have been roughly as follows:

Lepine and others have declared the existence of glycolytic ferments in all tissues—not merely in the pancreatic secretion—and have regarded them as the universal agents promoting the oxidation of sugars. Stoklasa and his pupils find in all organs a ferment which decomposes carbohydrates with the formation of alcohol and carbon dioxid, and Feinschmidt, too, speaks of glycolysis as an independent process not even necessarily bound to the living cell. On the other hand attention has been called more recently to the possible part played by the pancreas in this process. Schade thinks of the whole process of decomposition of sugar as probably a catalytic process for which there are many analogies, and suggests that the internal secretion of the pancreas may be a catalyzer. Rahel Hirsch has found that there is a "proferment" in the pancreas which aids glycolysis in the liver; and about the same time Cohnheim announced in several papers that he had demonstrated that an extract of the pancreas was actually necessary to glycolysis in the muscles. By studying a mixture of glucose and muscle juice he showed that very little glycolysis (evidenced by the disappearance of the sugar) occurred, but that if an extract of pancreas were added the sugar disappeared very rapidly. This extract, he states, can be boiled and is soluble in alcohol; it is therefore not a ferment, but behaves as an activator to the enzymes normally present in the muscle. When added in excess it inhibits the action of the enzymes, possibly by deviating it from its relations with the sugar. This forms a very tempting explanation of the hyperglycemia in pancreatic diabetes, and it is just at this point that we feel it most likely that the internal secretion of the pancreas should act. Arnheim, Rosenbaum, Hall, De Witt and others have supported him, but Claus and Embden have repeated his experiments as exactly as they could and have found no effect from the pancreatic extract on the disappearance of sugar. With all possible modifications they have repeated their work, but the result is the same and they offer no explanation unless it be the obvious possibility that bacteria may have played a part, an objection which may be made to all these complicated experiments in which nutritive solutions must be kept for hours in a thermostat. Cohnheim replies that their results depend on neglect of the inhibition by excess produced by the activator or perhaps on the use of salt solution in their extracts, but admits that unless special care be taken to get the muscle free from blood its juices alone are active to a certain

[1] In this article the term "adrenalin" is used in quotin[illegible] of European and American authors without reference t[illegible] [illegible] 's make.

could occur, would that explain all the features of pancreatic diabetes? It is known that the general oxidation is maintained at about the normal level and it seems evident that the lack of carbohydrate metabolism merely requires the intensification of protein and fat metabolism with the results mentioned above.

From all this it appears that the direct demonstration of the nature and mechanism of the influence of the pancreas on metabolism is in no very satisfactory state. Its extirpation produces profound disturbances which are far more intense than can be produced in any other way, while we are as yet practically unable to annul these effects with any extract from the gland.

That it does not act quite independently of the other organs of internal secretion is evident, however, from a whole series of observations on the effects of hypersecretion or hyposecretion of these organs on the supposed field of activity of the pancreas. In nearly every instance the occurrence or non-occurrence of glycosuria has been adopted as the test and a complicated network of effects has been woven about this test. In itself glycosuria can be produced by a great variety of measures, some of which act by way of the nervous system; others, such as cantharidin, the salts of many metals and phloridzin, seem so to affect the kidneys that they become permeable for sugar and allow of a glycosuria even when there is little or no hyperglycemia. This latter group we may set aside at once, but the others seem to bear a closer relation to the activities of the pancreas itself, or, at any rate, to the structures which it influences. Thus the diabetic puncture of Claude Bernard which consists in puncturing a certain point in the floor of the fourth ventricle of the brain, the stimulation of sensory nerves which acts reflexly, the direct stimulation of the splanchnic sympathetics or their chemical stimulation by asphyxia or asphyxiating agents such as ether, morphin, etc., or by drugs such as caffein, diuretin, etc., all produce glycosuria with hyperglycemia. Some of them act on the more sensitive central nervous elements, while others, such as caffein and adrenalin can stimulate the peripheral terminations of the nerves. In accordance with this the effects of some are annulled by cutting the splanchnics, while others are not.

Nishi, in studying diuretin glycosuria, cut the sympathetic nerves one after another and found that the glycosuria depended on the transmission of impulses, not to the liver, but to the adrenals; hence he thinks that the action of the sympathetics is through the mechanism of epinephrin secretion. Extirpation of the adrenals removes their influence in the way of producing glycosuria, and as Zuelzer, Dohrn and Marx, Frouin and Mayer have shown, this operation annuls the glycosuric effect even of extirpation of the pancreas. It is evident then that the adrenals are extremely important as a link in the production of glycosuria by any of these insults to the nervous system. It is difficult to conceive of the exact mechanism of its action, but we have the following evidence. Injections of adrenalin produce hyperglycemia and glycosuria and greatly intensify the glycosuria already existing in depancreatized dogs. Efforts have been made to explain this as a direct action on the pancreas (Herter, Edmunds and others), and Edmunds regards it as not specific but merely a vasoconstrictor action which incapacitates the pancreas by rendering it anemic; but this position seems to be rendered untenable by the observations of Eppinger, Falta and Rudinger and others that in the absence of the pancreas the glycosuria is intensified by adrenalin. On the other hand Zuelzer, Embden and others have found that when it is added to the blood used in perfusing an excised liver it causes the liver to liberate sugar into the hepatic vein in far greater amount than when normal blood is used. No observations seem to have been made on the isolated action of the adrenal on the muscles with regard to the liberation of sugar. Taking all these things into account it seems that the weight of evidence is in favor of the idea that the adrenal secretion is the instrument of the nervous effects on the sugar depots of the body; that it by itself can in some way stir up the tissues to set free sugar into the circulation or mobilize the carbohydrate. The exact nature of this process, which seems to be a chemical one, is not clear to us. The experiments which are made by injecting adrenalin are very violent and crude and the dose must be enormous as compared with the amount of adrenal secretion normally poured into the veins. Ritzman has found that if one use a sufficiently dilute solution (1 to 2,000,000) it can be allowed to flow into the vein at the rate of 2 c.c. per minute and never produce glycosuria. If a more concentrated solution be used or this solution run in faster glycosuria does result. Evidently the pancreas is able to overcome and oxidize any excess of sugar set free by so small an amount, but is overtaxed by the results of the larger dose, and this gives us a hint as to the extraordinarily delicate balance maintained by the organs with regard to the circulating sugar. If, now, as Zuelzer has shown, we introduce the lymph from the thoracic duct, which may be supposed to contain much of the pancreatic secretion, with the adrenalin the balance is restored and no glycosuria results. One may perhaps regard the whole picture as being made up, not of the antagonism of two organs, but rather of the exercise of two separate functions—metabolism of sugar and glycolysis—the balance between which it is not easy to maintain in such rough experiments, so that when sugar mobilization predominates, glycosuria ensues.

Another phase of the question is brought to light when we consider the relation of the thyroid to these functions. The introduction of an excess of the thyroid secretion often leads to glycosuria. This is the explanation generally given of the glycosuria in Graves' disease. On the contrary, the extirpation of the thyroid (preserving the parathyroid intact) has quite the opposite effect. Then it is difficult to produce alimentary glycosuria (McCurdy, Falta, and others); the injection of adrenalin no longer produces glycosuria in the strength of solution formerly used (R. Hirsch, Falta, and others); and the glycosuria following the administration of ether is no longer obtainable (Grey and de Sautelle). When tetany is produced by simultaneous removal of the parathyroids the results are quite different, and the glycosuria is even accentuated (Falta). Even the glycosuria following pancreatectomy is diminished by extirpation of the thyroid.

In all these experiments, too, the criterion by which the results have been judged is the occurrence of glycosuria, but it seems that a deeper insight into the p
of the processes might have been gained if they h
considered with regard rather to the steps whic
glycosuria.

Thus King, who carried out his work in
of the Hunterian Laboratory, found that

mesentery, marked out by a black ligature, showed only a thin film of opalescent tissue composed practically entirely of islands of Langerhans. At this time the remainder of the pancreas was extirpated and after a transient glycosuria the dog recovered completely and was able to take by mouth nearly 40 gm. of glucose at one dose without showing any glycosuria. The subsequent extirpation of the film of tissue which had been left behind caused the development of the most intense and persistent glycosuria. The inference seems justified that the islands of Langerhans alone are able to maintain carbohydrate metabolism.

Interesting results which bear on the nature of the pancreatic function are brought forward by Forschbach, who produced the condition of parabiosis in two animals. The effect of the extirpation of the pancreas in one was annulled by its connection with the other. Since this was a vascular connection only, nervous influences could be ruled out and the symptoms must have been prevented by some substance passing from one animal to the other. In spite of this apparently conclusive evidence of the existence of some internal secretion of the pancreas we have not been able to demonstrate it satisfactorily by positive methods as in the case of the thyroid, although Zuelzer claims to be able with a deproteinized extract of the pancreas to annul the glycosuria which follows pancreatectomy. Indeed, we are not even informed as to where such a secretion must exert its function.

It has been shown that in most cases after extirpation of the pancreas, the liver and other normal depots are extremely poor in glycogen, and Ivar Bang makes the statement that the function of the internal secretion of the pancreas is to control the storage of sugar in this form—without it there must be an excess of soluble sugar in the blood and consequently glycosuria. A moment's reflection will make clear, however, that this could not in itself explain the phenomena of pancreatic diabetes, for when the pancreas is extirpated in hungering and glycogen-free animals there suddenly appears, without the intake of any carbohydrates, a great excess of circulatory sugar and glycosuria. The disturbance is far deeper than the mere inability to polymerize and store sugar. There is actually a new formation of sugar from proteins and from fats; even the tissues are consumed, and that portion of their molecules which will form sugar is set free as such in the circulating blood. Nor can we find a satisfactory explanation in disturbances in the activity of diastatic ferments which set free the sugar from its polymerized form. It seems quite possible that the pancreas may control this in some way, allowing only so much as is necessary to be turned into the circulation, so that when its influence is lost, mobilization of the sugar is too rapid. In this sense it is actually found (Zuelzer, Falta and others) that the addition of pancreatic extract to adrenalin will prevent the production of glycosuria by that substance, and that the constip[illegible]tion of the pancreas by pilocarpin will in some unable t[illegible]o prevent the production of adrenalin[1] glycohand unt[illegible]till it is obvious as before that this cannot be use the [illegible] for the changes in pancreas diabetes, for as adenoids r[illegible]id, they appear in hungering animals in *Physical* [illegible]s no glycogen to saccharify so that the throughout c[illegible] still deeper.

eyes react to [illegible] is carried to the tissues by the blood and cannot co[illegible] in the tissues it is oxidized to furnish warmth and energy, but it appears that this oxidation is not easy unless the sugar be first split into somewhat simpler substances, a process which may be spoken of as glycolysis and conceived of as being carried out by a glycolytic ferment. The most earnest efforts have been made to determine the existence of such ferments in the body and if possible to ascertain the relation they bear to the pancreas. The results have been roughly as follows:

Lepine and others have declared the existence of glycolytic ferments in all tissues—not merely in the pancreatic secretion—and have regarded them as the universal agents promoting the oxidation of sugars. Stoklasa and his pupils find in all organs a ferment which decomposes carbohydrates with the formation of alcohol and carbon dioxid, and Feinschmidt, too, speaks of glycolysis as an independent process not even necessarily bound to the living cell. On the other hand attention has been called more recently to the possible part played by the pancreas in this process. Schade thinks of the whole process of decomposition of sugar as probably a catalytic process for which there are many analogies, and suggests that the internal secretion of the pancreas may be a catalyzer. Rahel Hirsch has found that there is a "proferment" in the pancreas which aids glycolysis in the liver; and about the same time Cohnheim announced in several papers that he had demonstrated that an extract of the pancreas was actually necessary to glycolysis in the muscles. By studying a mixture of glucose and muscle juice he showed that very little glycolysis (evidenced by the disappearance of the sugar) occurred, but that if an extract of pancreas were added the sugar disappeared very rapidly. This extract, he states, can be boiled and is soluble in alcohol: it is therefore not a ferment, but behaves as an activator to the enzymes normally present in the muscle. When added in excess it inhibits the action of the enzymes, possibly by deviating it from its relations with the sugar. This forms a very tempting explanation of the hyperglycemia in pancreatic diabetes, and it is just at this point that we feel it most likely that the internal secretion of the pancreas should act. Arnheim, Rosenbaum, Hall, De Witt and others have supported him, but Claus and Embden have repeated his experiments as exactly as they could and have found no effect from the pancreatic extract on the disappearance of sugar. With all possible modifications they have repeated their work, but the result is the same and they offer no explanation unless it be the obvious possibility that bacteria may have played a part, an objection which may be made to all these complicated experiments in which nutritive solutions must be kept for hours in a thermostat. Cohnheim replies that their results depend on neglect of the inhibition by excess produced by the activator or perhaps on the use of salt solution in their extracts, but admits that unless special care be taken to get the muscle free from blood its juices alone are active to a certain degree. All these experiments were performed with admixture of antiseptics, and Stoklasa rather both objects that this removes them far from physiologic conditions. It seems true that they would be crude and not entirely satisfactory even if the results were in unison, but with such contradictions among competent workers it is difficult to estimate precisely the standing of the pancreatic activator. In these experiments further, no attention is paid to the end-results of the reaction—the first splitting of the sugar which renders it incapable of reducing copper is as far as they go.

If, however, we could feel sure that without the pancreatic secretion no glycolysis or oxidation of sugar could occur, would that explain all the features of pancreatic diabetes? It is known that the general oxidation is maintained at about the normal level and it seems evident that the lack of carbohydrate metabolism merely requires the intensification of protein and fat metabolism with the results mentioned above.

---

[1] In this article the term "adrenalin" is used in quoting the work of European and American authors without reference to any particular firm's make.

From all this it appears that the direct demonstration of the nature and mechanism of the influence of the pancreas on metabolism is in no very satisfactory state. Its extirpation produces profound disturbances which are far more intense than can be produced in any other way, while we are as yet practically unable to annul these effects with any extract from the gland.

That it does not act quite independently of the other organs of internal secretion is evident, however, from a whole series of observations on the effects of hypersecretion or hyposecretion of these organs on the supposed field of activity of the pancreas. In nearly every instance the occurrence or non-occurrence of glycosuria has been adopted as the test and a complicated network of effects has been woven about this test. In itself glycosuria can be produced by a great variety of measures, some of which act by way of the nervous system; others, such as cantharidin, the salts of many metals and phloridzin, seem so to affect the kidneys that they become permeable for sugar and allow of a glycosuria even when there is little or no hyperglycemia. This latter group we may set aside at once, but the others seem to bear a closer relation to the activities of the pancreas itself, or, at any rate, to the structures which it influences. Thus the diabetic puncture of Claude Bernard which consists in puncturing a certain point in the floor of the fourth ventricle of the brain, the stimulation of sensory nerves which acts reflexly, the direct stimulation of the splanchnic sympathetics or their chemical stimulation by asphyxia or asphyxiating agents such as ether, morphin, etc., or by drugs such as caffein, diuretin, etc., all produce glycosuria with hyperglycemia. Some of them act on the more sensitive central nervous elements, while others, such as caffein and adrenalin can stimulate the peripheral terminations of the nerves. In accordance with this the effects of some are annulled by cutting the splanchnics, while others are not.

Nishi, in studying diuretin glycosuria, cut the sympathetic nerves one after another and found that the glycosuria depended on the transmission of impulses, not to the liver, but to the adrenals; hence he thinks that the action of the sympathetics is through the mechanism of epinephrin secretion. Extirpation of the adrenals removes their influence in the way of producing glycosuria, and as Zuelzer, Dohrn and Marx, Frouin and Mayer have shown, this operation annuls the glycosuric effect even of extirpation of the pancreas. It is evident then that the adrenals are extremely important as a link in the production of glycosuria by any of these insults to the nervous system. It is difficult to conceive of the exact mechanism of its action, but we have the following evidence. Injections of adrenalin produce hyperglycemia and glycosuria and greatly intensify the glycosuria already existing in depancreatized dogs. Efforts have been made to explain this as a direct action on the pancreas (Herter, Edmunds and others), and Edmunds regards it as not specific but merely a vasoconstrictor action which incapacitates the pancreas by rendering it anemic; but this position seems to be rendered untenable by the observations of Eppinger, Falta and Rudinger and others that in the absence of the pancreas the glycosuria is intensified by adrenalin. On the other hand Zuelzer, Embden and others have found that when it is added to the blood used in perfusing an excised liver it causes the liver to liberate sugar into the hepatic vein in far greater amount than when normal blood is used. No observations seem to have been made on the isolated action of the adrenal on the muscles with regard to the liberation of sugar. Taking all these things into account it seems that the weight of evidence is in favor of the idea that the adrenal secretion is the instrument of the nervous effects on the sugar depots of the body; that it by itself can in some way stir up the tissues to set free sugar into the circulation or mobilize the carbohydrate. The exact nature of this process, which seems to be a chemical one, is not clear to us. The experiments which are made by injecting adrenalin are very violent and crude and the dose must be enormous as compared with the amount of adrenal secretion normally poured into the veins. Ritzman has found that if one use a sufficiently dilute solution (1 to 2,000,000) it can be allowed to flow into the vein at the rate of 2 c.c. per minute and never produce glycosuria. If a more concentrated solution be used or this solution run in faster glycosuria does result. Evidently the pancreas is able to overcome and oxidize any excess of sugar set free by so small an amount, but is overtaxed by the results of the larger dose, and this gives us a hint as to the extraordinarily delicate balance maintained by the organs with regard to the circulating sugar. If, now, as Zuelzer has shown, we introduce the lymph from the thoracic duct, which may be supposed to contain much of the pancreatic secretion, with the adrenalin the balance is restored and no glycosuria results. One may perhaps regard the whole picture as being made up, not of the antagonism of two organs, but rather of the exercise of two separate functions—metabolism of sugar and glycolysis—the balance between which it is not easy to maintain in such rough experiments, so that when sugar mobilization predominates, glycosuria ensues.

Another phase of the question is brought to light when we consider the relation of the thyroid to these functions. The introduction of an excess of the thyroid secretion often leads to glycosuria. This is the explanation generally given of the glycosuria in Graves' disease. On the contrary, the extirpation of the thyroid (preserving the parathyroid intact) has quite the opposite effect. Then it is difficult to produce alimentary glycosuria (McCurdy, Falta, and others); the injection of adrenalin no longer produces glycosuria in the strength of solution formerly used (R. Hirsch, Falta, and others); and the glycosuria following the administration of ether is no longer obtainable (Grey and de Sautelle). When tetany is produced by simultaneous removal of the parathyroids the results are quite different, and the glycosuria is even accentuated (Falta). Even the glycosuria following pancreatectomy is diminished by extirpation of the thyroid.

In all these experiments, too, the criterion by which the results have been judged is the occurrence of glycosuria, but it seems that a deeper insight into the p of the processes might have been gained if they h considered with regard rather to the steps whic glycosuria.

Thus King, who carried out his work in of the Hunterian Laboratory, found that thyroid juice to the Cohnheim mixtur and muscle juice with sugar, marked glycolysis. This seems to give a simple ex the significance of the thyroid in this connecti we have the balance of the adrenal function of mobilizing sugar and the pancreatic function of glycolysis

affected by a chemical substance. It is as though, as Schade suggests, the glycolytic ferment were a sort of catalyzer which might be thought of as affected by the thyroid secretion as catalase may be affected by cyanids. This seems to me much simpler than the hypothesis that the activity of the pancreas itself is in some way inhibited by the activity of the thyroid.

We know so little about the action of the hypophysis that it is difficult to discuss it here; but it may be recalled that glycosuria sometimes occurs in disease of the hypophysis, and Borchardt has been able to produce it by injections of hypophyseal extract.

Eppinger, Falta, and Rudinger have made a great many of these experiments, and have added much to the knowledge of the interrelation of the organs of internal secretion. These interrelations they attempt to express in the form of a scheme in which the thyroid, pancreas, and chromaffin system are shown in their relation to one another. In this triangle the thyroid and pancreas are represented as mutually inhibiting one another's activities; so, too, the pancreas and chromaffin system; while the thyroid and chromaffin system promote the activities of one another. On this basis they can explain, without too much forcing, all or nearly all of the phenomena. It must be said, however, that this seems to be merely stating in rather vague phraseology the results, of which we know so little, of the mechanism, and there can be no doubt, in spite of the possible value of this scheme in suggesting further experiments, that a satisfactory explanation can rest only on definite chemical studies.

To me it seems more probable that the chromaffin system is concerned, not with the activity of the pancreas, but with the mobilization of sugar; that the pancreas is similarly concerned, not with inhibiting the activity of the adrenals, but with causing the glycolysis of the free sugar; while the secretion of the thyroid, if in excess, interferes with this glycolytic action of the pancreatic ferment. How far the other organs of internal secretion are concerned in this usually smoothly working mechanism remains to be discovered.

The literature on any other internal secretion of the pancreas is relatively meager, and most investigators take it for granted that the appearance of fat in the stools in depancreatized animals is merely the effect of the loss of the fat-splitting ferment of the external secretion. The lipemia which sometimes occurs even in human cases of diabetes can not be explained thus, however, and Lombroso has shown that more fat appears in the stools than is taken in with the food, and that it has different characters and a higher melting point than that fed. It must be reexcreted into the intestine. The ligation of the pancreatic duct seems not to produce any such extreme disturbance in the fat metabolism, and on that account the suggestion is made that there may be an internal secretion governing this. Further investigations of this point are necessary.

PRESENT KNOWLEDGE OF THYROID FUNCTION

S. P. BEEBE, M.D.
Professor of Experimental Therapeutics, Cornell University Medical College
NEW YORK

At the present time we know that the thyroid gland fills a very important function in the animal body. We do not know the precise details as to how this function is fulfilled, and because of our lack of knowledge on this point we may more readily turn the discussion to the consideration of theories than is the case in regard to the other tissues which have been more thoroughly studied and concerning which we have more definite information.

One of these theories is deserving of recognition merely for the purpose of rejection. I refer to the ideas sponsored by Blum, Notkin and others—the so-called neutralization theory. These investigators have stated that the function of the thyroid is to detoxicate certain metabolic products which arise in the animal body, and this action they conceive to take place in the thyroid itself and to be accomplished by the union of iodin with the metabolic product. By such a means the toxic, deleterious effects of these products are prevented, and one of the strongest arguments in support of their theory has been the experiment of Blum who showed that if the secretion from the thyroid gland was artificially combined with iodin, it no longer had characteristic thyroid effects. The more completely these proteins are saturated with iodin the less harmful they are.

Such being the case, it follows that if the extracts of the gland contain little iodin, we should expect very active toxic effects from it since the metabolic toxins have been only partially rendered innocuous. Second, it must follow that if the action takes place only within the thyroid gland, removal of the thyroid must render it impossible for thyroid function to be subserved in such an animal. We know that both of these propositions are incorrect. We know that if thyroid protein is administered to animals and patients in whom the gland is entirely lacking, or pathologically so damaged as to be incapable of function, it causes such physiologic changes as to make the animal in most respects normal. The proper functioning of the extract does not require the presence of the gland.

It must be evident, therefore, that the physiologic action of this secretion is exerted on other tissues than the thyroid. We know, likewise, that thyroids containing little iodin show comparatively little of the characteristic thyroid effect, while those containing much iodin are much more active physiologically. There is absolutely no reason whatsoever for supposing that the artificial addition of iodin to the thyroid protein *in vitro* is in any way comparable to the action which is accomplished by the epithelial cell of the gland. No artificially prepared iodin-containing substance has an effect similar to that of thyroid secretion, or can be used as a substitute for thyroid secretion. Both of these conclusions are well established and they are sufficient to controvert successfully the belief that the thyroid function is entirely accomplished within the gland itself. The function of the gland is to produce a substance which is absorbed into the circulating fluids of the body to act on some of the distant tissues, and it probably is not of benefit to the animal for physiologic purposes except as reserve material while it remains in the gland. Except for the fact that the gland does not have a *definite duct,* there is no reason why it should be classed with the glands of internal secretion.

We know that the physiologically active portion of the gland secretion is a protein substance containing iodin in a specific organic combination. The iodin is probably combined with some aromatic group in the molecule. Precisely what its structure is, we do not know. No substance having similar properties has ever been prepared in the laboratory. It does not seem probable that there is only one kind of protein substance which contains iodin. There is a very wide variation in the size of the normal thyroid gland and likewise in the iodin content of the protein taken from glands of individuals who have no apparent thyroid abnormality, as regards either structure or function.

If one attempts to separate the proteins from the thyroid gland into various groups, one finds it possible to obtain a number of different fractions, all of which are true proteins and all of which contain iodin, though the iodin content varies widely. I have never been able to obtain a definite protein or proteose from the thyroid absolutely free of iodin. This is contrary to the findings of many other investigators. The protein which in my experience answers all the physiologic requirements is readily prepared from normal thyroid glands by extracting the pulverized tissue with physiologic salt solution, filtering through gauze and paper pulp and from this clear filtrate obtaining a precipitate by acidifying with acetic acid and heating to 44 C. This protein corresponds to the thyroglobulin described by Oswald. From the clear filtrate other proteins and proteoses may be separated by heating to a higher temperature, and by the addition of various salts. As previously stated, all these protein fragments contain iodin, but the protein first separated contains a much larger percentage of iodin than any of the others. In extracts of beef and pig glands, acetic acid gives an abundant precipitate before heating, but in human and sheep glands, the heating is necessary to cause a separation of protein.

It seems probable that the thyroid function is dependent on the presence of iodin in the molecule and most investigators are agreed that the physiologic activity of the secretion is at least roughly proportional to the iodin content. I believe that we do not yet have convincing evidence that iodin-free thyroid has characteristic function. Hunt has devised a quantitative method for measuring thyroid activity depending on the protection of mice to aceto-nitrile poisoning. In his hands this method has yielded most remarkable results. In my judgment the iodin value is quite as accurate and much simpler in application.

We have yet no evidence to show that differing qualitative effects are produced by thyroid from different types of glands with different iodin values. The normal thyroid contains alveoli filled with the colloid substance which is largely made up of the particular globulin having characteristic thyroid activity. The quantity of this particular protein varies widely in different glands. No structure in the body shows such marked changes in its histologic characteristics as the thyroid.

The facilities for the absorption of this material are apparently not such as to provide for taking up a large quantity in a short space of time, and the question arises as to how large an amount of this material must enter the circulation in a unit of time in order to satisfactorily carry on the thyroid function. As far as we can judge from experimental conditions, the sensitiveness of different animals and different individuals to thyroid shows wide variations. In some instances I have produced noticeable effect in a human adult by the hypodermic administration of 5 mg. of protein prepared as above from normal glands containing between 0.32 and 0.36 mg. of iodin per gram of fresh gland. In other cases, 0.01 gm. has shown decided activity, while 0.06 gm. usually shows quite pronounced effects even in normal individuals. In several cases of cretinism I have found 0.01 gm. of this protein has been effective in completely ameliorating symptoms. In myxedema, 0.03 gm. of these proteins taken each day has kept the symptoms completely under control. On the other hand, I have had individuals taking 0.5 gm. daily for considerable periods without producing any other effect, as far as could be determined, than that of general well-being. There is then a very wide variation between the limits of the amount required to maintain health and the amount which an individual may take without causing marked physiologic disturbance. Furthermore, if so small a quantity of protein as that mentioned is sufficient to satisfy the needs of the average individual for thyroid function, we need not suppose that the venous blood or the lymph coming from a thyroid should contain very much of this secretion. Three-hundredths of a gram of this protein put into the blood which flows through a normal gland in one day (and this has been estimated by Kraus to be fourteen times the total volume of blood in the body) would not give an appreciable addition in iodin. It furthermore indicates what a large factor of safety there is in a normal thyroid gland. Such a gland would average about 20 gm. in weight from which there might be obtained 3 gm. of the protein above used or one hundred times the quantity sufficient to fill the demand for this secretion in the case of a myxedematous patient.

Since the isolation of iodothyrin by Baumann it has been believed that the thyroid function might be served by the use of this small fragment of the protein, but it is my belief that the thyroid function is not in all respects to be filled by this fragment. The physiologic as well as the most effective method of administering thyroid secretion to an animal is to give the same biologic sort of secretion by hypodermic injection. I have in many instances been unable to get the same quality of effect or to produce the same change in the metabolism of an animal by administering thyroid by mouth as could be obtained when giving it directly into the circulation. We do not know on what tissue or set of tissues the thyroid secretion acts. It does not seem to me probable that it is to be compared to the exclusive action of secretin, but rather that most of the tissues in the body are in some way affected by this substance, perhaps in part through the medium of the nervous system. We know that it is connected in some way with the function of oxidation in the body. By the administration of thyroid to a cretin or patient with myxedema it is possible to increase the absorption of oxygen from 20 to 75 per cent. There is a corresponding increase in the amount of heat give off from the body. The removal of the thyroid i could animal will cause diminution in the absorption t ensued, gen which may be again increased by thyroid . Administration of thyroid to a normal animal F. The an increase of from 10 to 40 per cent. in some diffi- no paralysis of demand. In comparing myxedema with C extremities were we find a very marked contrast in this be obtained only the former the absorption of oxygen, such as traction of ment, the energy exchange is often not more 30 p. m. on 50 per cent. of the normal, while in the latter toward these factors very much increased, occasionally to nearly double the normal. We are again confronted by our lack of knowledge when we find that these changes do not always follow thyroid administration.

On the same diet the nitrogen excretion is less when the animal is deprived of the thyroid and markedly increased when thyroid is again given. Such a result is probably merely secondary to the question of oxidation in the different tissues. We do not know why this increased oxidation and nitrogen loss follows administration of thyroid, but Schryver has found that the liver of animals that have been fed on thyroid show during the first twenty-four hours more rapid autolysis than controls. Wells has found that the addition of thyroid to the autolyzing liver has no effect in this respect, but such an experiment is not exactly comparable to Schryver's and does not controvert the accuracy of his results. It seems probable some change has been effected in the liver cell making it more susceptible to autolytic destruction. But a point of great interest is that if the animal is fed for some time on thyroid the rapid autolysis is not seen. A somewhat similar phenomenon is seen in some cases of thyroid feeding to obese persons. A small quantity of thyroid will in the beginning cause a comparatively rapid loss in weight from 10 to 30 pounds, but then a refractory period is reached when a large quantity will cause little or no changes. The character of the nitrogenous metabolism, that is, the distribution of various nitrogenous constituents in the urine, is not markedly different in cases of myxedema and Graves' disease, but I have recently observed instances in which toxic symptoms of somewhat varying type have been associated with high ammonia and high rest nitrogen fractions in the urine and in which complete symptomatic relief and normal nitrogen divisions in the urine followed the administration of thyroid. It is not possible to say that these individuals were suffering primarily from a lack of thyroid function since there was no other evidence than the facts which I have stated.

The nitrogen requirement to maintain equilibrium is increased by the addition of thyroid. It has been observed that the protein-sparing power of carbohydrate is less rapidly manifested in the metabolism experiments on animals being fed with thyroid. We may compare such experiments to conditions found in patients suffering from exophthalmic goiter. We find during certain of the acute phases of the disease that the nitrogen requirements are very high indeed. I have seen a patient in the toxic phases lose weight and show a marked nitrogen loss when she was receiving a diet so rich in carbohydrate that she had an alimentary glycosuria; and with a nitrogen intake of 22 gm. the nitrogen loss at the same time was 4.5 gm. It is not possible to feed such persons a sufficient quantity of any form of diet to entirely prevent nitrogen loss. Such patients may show an elevation of temperature, 1 to 1.5 degrees. They are usually very nervous, although physically weak, and it is evident that we are not dealing here with physiologic conditions in metabolism in which the usual processes for preventing nitrogen loss are available, but that the excessive quantity of thyroid secretion [illegible] altered the metabolic processes that we have a [illegible]truction corresponding to what takes place in [illegible] infections. Such a phase of the disease does [illegible]t long.

[illegible] function is in some way concerned with [illegible] metabolism. Repeated observations have [illegible] showing that the administration of thyroid [illegible]wers the assimilation or retention of carbohydrate more difficult. Certain facts in regard to this matter have been observed clinically. In severe Graves' disease an alimentary glycosuria is not rare and occasionally a severe and rapidly fatal diabetes develops after this disease when all the other symptoms have been relieved or have abated. In myxedema, on the contrary, the limits of assimilation for carbohydrate are much above those observed normally. In relation to this matter, I will mention an instance of severe fatal diabetes occurring in a woman of 53 after recovery from Graves' disease. In this case, the administration of thyroid to the patient caused a marked increase amounting to 90 per cent. in the quantity of sugar excreted as well as marked increase in the excretion of diacetic acid, oxybutyric acid and acetone. The patient at this time had no symptoms of Graves' disease. There was no reason to suppose that the diabetes was in any way concerned with the hyperfunction of the patient's own gland.

One can scarcely discuss this question without referring to the theories which have been advanced by Falta and his co-workers. The supposed interrelations between the thyroid, pancreas and adrenal, which they have worked out, are suggestive and possibly point to a future explanation of some of these matters. The experimental results which they have used thus far to substantiate their theory are only suggestive, and in my judgment they have proved nothing more than that further investigation along those lines is necessary.

The reaction on the pupil of the enucleated frog's eye has been used to show an antagonistic action between the adrenal and the thyroid. Such a reaction indicates that we may get some antagonistic action between these two glands, but although we must suspect that the thyroid is closely related with other glands in the body, and we may say that we know that such interrelations probably exist, the majority of these theories regarding these interrelations are based on pathologic and clinical observations and not on accurate experimentation.

Attempts have been made to demonstrate that the thyroid gland serves a particularly valuable function in combating infections in the body. The expressed juices of the thyroid have been allowed to act directly on bacteria with apparent bactericidal effect, but not in any respect more than was obtained from extracts of the liver and kidney. The quantity of the alexin in the blood has been found to be increased in those animals to which thyroid has been given, and it is a commonly observed fact that cretinous and myxedematous patients do not bear infections well, while on the other hand certain observers believe that every infection stimulates the thyroid to additional activity. It is certainly open to question whether a specific effect in infections is to be ascribed to the thyroid. It rather appears that the effect is a general one and it seems improbable that the thyroid function is one of the specific means by which the body protects itself from infectious diseases.

From the evidence which is now obtainable I think we must conclude that the thyroid gland furnishes a hormone which may be present in the blood within wide limits in the condition which we call health, and which stimulates a variety of tissues to a physiologic, and at times a pathologic, degree of activity.

Occupation in Treatment of Neurasthenia.—Healthy occupation of body and mind, says D. Ferrier in the *Practitioner*, never does any harm to the most pronounced neurasthenic, but the reverse. If work at first is hard, it becomes easier by degrees, and patients who find the régime a hard one should be told that it is better to be ill at work than ill in idleness. The misfortune is that so many neurasthenics have *neither* the determination nor the courage to submit to the necessary training of their morals, and thus go to swell the crowd of able-bodied valetudinarians.

REPORT OF A CASE OF EPIDEMIC ANTERIOR POLIOMYELITIS

DIAGNOSIS IN PREPARALYTIC STAGE BY LUMBAR PUNCTURE

LEWIS F. FRISSELL, A.M., M.D.
Associate in Medicine, Columbia University; Visiting Physician, Seton Hospital
NEW YORK

The patient, a young man of 21, was a member of the freshman class at Princeton, where he had been in attendance for five weeks before the onset of symptoms. At his home in Bernardsville, N. J., no cases of poliomyelitis were known to have occurred. At Princeton during the summer there had been several cases of the disease and in the college three cases, all in the freshman class, two of them fatal. The patients had all come from infected localities, though the disease did not appear until those attacked had been from two to five weeks in Princeton. The men did not know each other or room in the same dormitory, the only point of contact being in commons or recitation room. The patient had been under my care for a number of years. The only significant thing in his past history was pneumonia four years ago, and a rather run-down condition a year ago, at which time tuberculosis was suspected. He had had a slight cold the week before from which he had practically recovered. Three weeks before the onset of symptoms he had attended the funeral of one of the men who died of the disease. On October 29 he suffered from malaise, headache and chilly sensation, but felt well enough to take the train for Washington. On the next day, however, as the symptoms continued and became more severe, he returned to college and, as his bowels had not moved since the 29th, on the evening of the 30th he took a dose of salts and vomited immediately; the vomiting was repeated several times during the night, but there was no movement of the bowels. The following day, October 31, there was slight pain in the back of the neck and sense of fatigue in the gluteal region.

The patient was first seen by me on the evening of October 31, fifty-six hours after the onset of symptoms. At this time his temperature was 101 F., his pulse 90, respiration 22. The pharynx was slightly reddened, the tongue coated, eyes normal, heart and lungs normal. The abdomen was soft, a trifle distended and tympanitic; there was no enlargement of the spleen and no rose spots. The reflexes were exaggerated, patella, Achilles tendon, wrist and elbow. An ankle-clonus was obtained on both sides. Kernig's and Babinski's signs were not obtained. There were no paralyses or even muscle weakness. The neck seemed a trifle stiff, but only in a strained position when the patient sat upright in bed. In the dorsal decubitus the chin was readily brought forward to the chest. As a positive diagnosis was impossible, the patient was brought to New York where he was seen in consultation by Dr. T. C. Janeway, who concurred in the negative results of the previous examination. A blood-count and blood-culture were made the same evening. : red cells, 5,020,000; hemoglobin, 92 per cent; color index, 0.92; leukocytes, 12,000; small lymphocytes, 30.2 per cent.; large lymphocytes, 4.8; polymorphonuclear, 64.0; eosinophils, 0.2; basophils, 0.2; plasmodia of malaria, none. The Widal test was negative in dilution of 1 to 20. The urine was acid clear,; albumin, faint trace; sugar, none; indican, trace; specific gravity, 1,028. Microscopic examination showed few leukocytes. In view of the negative finding on physical examination, and in the blood and urine, it was resolved to wait for the result of the blood-culture, which might be expected to show *Bacillus typhosus*, were it present, and in the absence of this, if symptoms persisted, to introduce a needle into the spinal canal.

On November 1 the patient was more comfortable, though there was some pain in the lumbar region. High temperature persisted. The bowels, which had not moved since the 29th, were finally moved by calomel salts and rectal irritation. The results were foul-smelling.

On November 2 fever persisted. The second blood examination shows a slight fall in polymorphonuclear cells and increase in the small lymphocytes. Polymorphonuclears were 59 per cent, lymphocytes 34 per cent. The physical examination was still negative, but all the reflexes were less active and the ankle-clonus had disappeared. Rigidity of the neck as before. The diagnosis at this point was still obscure. The patient might have typhoid fever, gastro-intestinal toxemia, one of the more slowly developing cases of meningitis, or poliomyelitis. As the blood culture was reported sterile, lumbar puncture was performed. There was a rapid drop flow and 10 c.c. of fluid obtained. The fluid was practically clear; only a slight shimmering appearance was noticed on shaking the tube. Dr. Simon Flexner, of the Rockefeller Institute, who kindly offered to examine the fluid, reported as follows:

"The first specimen, received on November 3, consisted of a limpid fluid, almost but not quite clear, and yet not turbid, showing on agitation a faint opalescence. On centrifugalization, the fluid yielded sediment containing a considerable number of small and a small number of large lymphocytes, and a very few polynuclear leukocytes. There were no red blood-corpuscles present. The perfectly clear supernatant fluid gave a marked protein reaction with Noguchi's butyric acid test. The specimen, therefore, contained excess of white corpuscles, chiefly lymphocytes, and of protein. The condition of the fluid resembled that seen in monkeys inoculated with the virus of epidemic poliomyelitis, just before the onset of paralysis."

As a result we felt that as tuberculous meningitis could be fairly excluded, a diagnosis of anterior poliomyelitis could be reasonably made; furthermore, that paralysis, if it ensued, would come shortly.

November 3, 9 a. m., temperature was still 101 F. The patient complained of muscular weakness and had some difficulty in turning in bed. There was, however, no paralysis of any muscle group. The reflexes of the upper extremities were still obtained, but the patella reflexes could be obtained only when the patient made a voluntary effort such as traction of the hands. No urine had been passed since 6:30 p. m. on November 2, but there was no evidence of enlargement upward of the bladder. The bowels had been moved with difficulty. At 2 p. m., inability to urinate continued. The bladder by

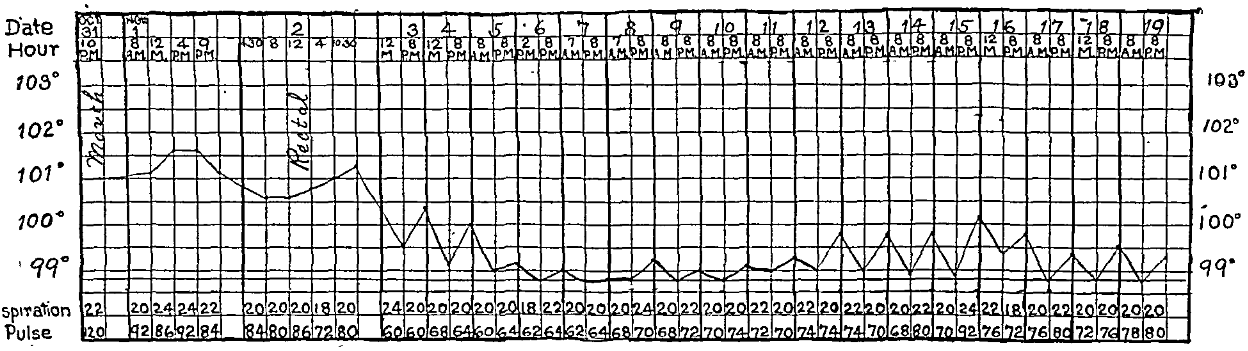

Chart of case of poliomyelitis.

percussion extended 2 inches above the symphysis pubis. On catheterization there was no free flow of urine and pressure over the abdomen was required. There was some general weakness in the legs and a sense of weight in the right leg on flexion. At 6 p. m. a complete examination of the muscular system was made which showed paralysis of the left hamstrings, weakness of the quadratus lumborum and the lower belly of the right rectus, and slight weakness of the erector spini group. There was a sense of weight in the right thigh when the leg was lifted in extended position. The calf peronei, extensors of feet, abductors and rotators of thigh were normal; muscles of head, face, eyes, shoulder-girdle and arms normal. The wrist, elbow, biceps and Achilles reflexes were present; knee-jerks lost on both sides. Paralysis thus appeared at the end of the fifth day of the disease, and the muscle groups affected showed the presence of disease of lumbar enlargement of the cord with fairly general distribution. With the appearance of paralytic symptoms the temperature fell, gradually reaching normal on November 6.

On November 4, lumbar puncture was again performed and 10 c.c. of fluid obtained by a rapid drop flow. The leukocytes showed a slight increase; the polymorphonuclears dropped to 63.5 per cent., the lymphocytes to 27.5 per cent. Dr. Flexner's report justified the belief that the height of the irritative stage had passed. It was as follows:

"The opalescence is less, so that the fluid is, to all intents, 'clear.' The sediment obtained by centrifugalization showed still an excess of lymphocytes, but the supernatant fluid showed a diminished reaction for protein. This second fluid resembled that of monkeys after the paralysis had set in."

On the following day weakness of the extensors of the left foot and the anterior tibial group was first noted.

Pain in the back and muscles of the thigh was becoming very troublesome and was relieved only by baths of a temperature from 105 F. to 110 F. This symptom persisted until December 10 with varying intensity.

On November 7 the patella tendon reflexes were again obtained.

November 9, Kernig's sign was obtained, but no Babinski. This symptom was thought to be due to the shortening of the posterior thigh muscles. Paralysis of the hamstring muscles was of varying intensity. As early as November 7 the legs could be flexed on the thigh, but with difficulty in the ventral decubitus. The bladder paralysis lasted for twelve days, and the bowels were moved only with great difficulty for a month.

On November 27, after the temperature had been normal for ten days, the electric reactions were tested by Dr. J. *Ramsay Hunt.*

Reaction of degeneration was nowhere present. All muscles responded to faradism, but the left hamstring and left anterior tibial, extensors of the foot and peronei were most sluggish in response, though all the muscles of both legs and thighs were affected. The reflexes of the lower extremities had again become exaggerated and a patella-clonus was obtained.

Within a month the patient was up, and in six weeks walking, though at the time of writing there is a slight drop-foot on the right side which requires correction by orthopedic apparatus in order to prevent contraction of the stronger calf muscle. The prognosis is good for a practically perfect functional result.

As to treatment, from the start a nasal spray of a weak hydrogen peroxid solution was used, on the theory that the unknown organisms might be eliminated through the nose and reinfection thus produced. In infected monkeys Flexner has proved the infectiousness of the nasal mucous membrane. Counter-irritation to the spine by cupping and mustard was also applied early. Hexamethylenamin (urotropin) was administered in the hope that formaldehyd might be set free in the spinal cord. For the pain nothing proved so efficient as the hot tub bath, which also enabled the patient to move with ease his weakened muscle groups.

To summarize, one is impressed with the difficulty of diagnosis of this disease in its acute stage, in which it may resemble any of the infections, especially typhoid fever, influenza or intestinal toxemia. The very slight rigidity of the neck and the increase in the activity of the reflexes, which at that time we thought might be due to a hypersensitive nervous system, were suggestive, but only the presence of an epidemic put us on our guard as to the possibility of the correct diagnosis.

The exaggeration of the reflexes, gradually diminishing, and disappearing at the time of paralysis, only to become again exaggerated later, is another point in evidence of the general nature of the disease which cannot be exclusively confined to the anterior horn cells.

The inestimable value of lumbar puncture cannot be too strongly insisted on. By its means a diagnosis was established, and the fact that paralysis would probably follow determined twenty-four hours before its onset. Finally, by a second puncture twenty-four hours after the onset of the paralysis, the fact was determined that the height of the paralysis had passed and that the paralytic stage was nearing an end. As a matter of fact, within eighteen hours we had the last evidence of progression in the lesion. The puncture had, in this case, both prognostic and diagnostic value. In view of the number of normal lumbar punctures reported, it is fair to say that Dr. Flexner reports that the increase in lymphocytes and increased protein reaction are present in the spinal fluid of his experimental monkeys for a period of only a few days and incidentally that this is the first case in which he has followed the corresponding reactions in man.

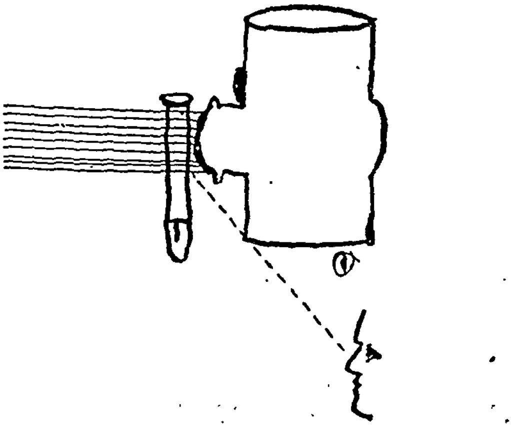
In conclusion, I wish to thank Dr. Flexner for his courtesy in examining the spinal fluid and for his many suggestions and keen practical interest in the case.

113 East Fifty-Sixth Street.

A SIMPLE METHOD FOR THE DETECTION OF MINUTE QUANTITIES OF ALBUMIN IN URINE

M. B. KATZENSTEIN, B.Sc., M.D., M.Sc.
PITTSBURG

On account of the difficulty experienced in detecting the presence of minute quantities of albumin in urine, I have been constantly on the lookout for a satisfactory method. I have found a solution of the difficulty, and the method applies both to contact and to the heat and acid tests. The method is a very simple one and consists in passing rays of light through the fluid and looking at it at right angles to the rays, the principle being the same as that of seeing particles of dust in a ray of sunshine. For light I use the original bull's-eye lantern



Method for the detection of minute quantities of albumin in urine.

used by nose and throat men for their reflected light. The detection of albumin is most satisfactorily done in connection with the heat and acid method. After heating and adding acid to the specimen the test-tube containing the fluid is held directly in front of the bull's-eye lantern and the specimen viewed from a point at right angles to the rays of light. In specimens in which I and others have failed to detect any cloudiness in all other lights, the cloudiness has stood out plainly when submitted to the above procedure. The urine should always be filtered, especially for the contact test. Any bull's-eye lantern will suffice. The great advantage of this method lies in the fact that it can be done at any time—night or day.

ABORTIVE CASES OF POLIOMYELITIS

AN EXPERIMENTAL DEMONSTRATION OF SPECIFIC IMMUNE BODIES IN THEIR BLOOD-SERUM *

JOHN F. ANDERSON, M.D.
Director Hygienic Laboratory, U. S. Public Health and Marine-Hospital Service

AND

WADE H. FROST, M.D.
Passed Assistant Surgeon, U. S. Public Health and Marine-Hospital Service

WASHINGTON, D. C.

It has been pretty generally recognized, since the publication of Wickman's studies on epidemic acute anterior poliomyelitis in Sweden in 1905-06,[1] that cases of this disease may run their course without resultant paralysis. The evidence on which the occurrence of such so-called "abortive" cases is predicated is, briefly, the following:

Especially in epidemics, cases of acute anterior poliomyelitis are encountered showing all gradations in the degree and extent of paralysis. In the same group may be found cases resulting in extensive and lasting paralysis; cases with permanent paralysis of slight extent; cases in which the patients have transient paralysis, recovering completely within a few weeks or even a few days; other cases in which there is no definite paralysis, but merely muscular weakness, of short duration; still others in which the only motor disturbance is ataxia, tremor or a transient ocular disturbance such as diplopia or nystagmus. Finally, within the same group are seen cases of illness exhibiting only the symptoms of a general infection, usually accompanied by symptoms indicative of meningeal, spinal or encephalitic irritation, but without definite motor disturbances.

The diagnosis of acute anterior poliomyelitis in these cases is suggested usually by their close association with typical cases of the disease rather than by the distinctiveness of their symptoms. The symptoms are, however, sufficiently similar to the pre-paralytic symptoms observed in paralytic cases, and in many instances sufficiently different from the symptoms observed in the more common infectious diseases to justify a provisional diagnosis of poliomyelitis. The similarity of these abortive cases to cases of frank poliomyelitis in the early stage, the signs of involvement of the nervous system, their close and constant association with frank paralytic cases, and the gradation of symptoms above mentioned had convinced many observers of the etiologic identity of abortive and paralytic cases of poliomyelitis even before any light had been thrown on the subject by the study of experimental poliomyelitis.

It has recently been noted by several observers that monkeys inoculated with the virus of poliomyelitis occasionally pass through an indefinite illness without resultant paralysis, clinically similar to abortive attacks as observed in man.

It has been shown by Levaditi and Landsteiner,[2] Römer and Joseph[3] and Flexner and Lewis[4] that the serum of monkeys which have recovered from poliomyelitis, mixed in suitable proportions with an emulsion of the virus and allowed to remain in contact for a sufficient length of time, renders the virus inactive, so that when injected into fresh monkeys it fails to produce the disease.

Netter and Levaditi,[5] and Flexner and Lewis,[4] have demonstrated the same property in the serum of human beings who have recovered from acute poliomyelitis. This property has been found by all the above observers to be absent from the serum of normal persons and monkeys, and has therefore been considered a specific property, the demonstration of which in the serum justifies the inference that the subject has passed through the infection of acute anterior poliomyelitis.

Netter and Levaditi,[6] availing themselves of this test, have also demonstrated this germicidal property against the virus of poliomyelitis in the serum of a suspected abortive case, thereby giving additional confirmation of the etiologic identity of such cases with frank poliomyelitis.

The clinical history of the abortive case tested by Netter and Levaditi is as follows (translation from the French):

> "CASE 3.—Henriette G., sister of Emile (see below), was with a nurse in L'Aveyron, returning in good health Dec. 15, 1909. Three weeks after her return the child fell off, lost appetite, became cross, showed less disposition to run about, complained of pain behind the knees when the legs were touched, and of the arms when they were pulled. These symptoms, which attracted the attention of Dr. Ergbischoff, caused no uneasiness to the rather heedless parents, who refused to show us the child on February 7. The mother thought the child was suffering from *mal du pays.* Whatever the trouble, it all disappeared in the course of three weeks. The child regained her normal appearance and showed every appearance of health the latter part of March."

A brother, Emile, 6 years old was taken ill either a few days before or a few days after this child (the dates given are not clear as to the sequence of cases) with a typical attack of acute anterior poliomyelitis, resulting in lasting paralysis of a leg and an arm.

The experiments which we here report are similar to the above experiment of Netter and Levaditi, undertaken on a more extensive scale, designed to throw some light on the diagnosis and epidemiologic significance of a class of cases encountered by one of us,[7] in a field study of acute anterior poliomyelitis at Mason City, Iowa, and other points in that state during the summer of 1910.

In Mason City, Iowa, a town of about 14,000 inhabitants, there occurred from April to September, 1910, forty cases of undoubted acute anterior poliomyelitis, resulting in typical flaccid atrophic paralysis. At the same time there occurred a considerable number of cases of illness with symptoms suggestive of the early symptoms of acute poliomyelitis, but not resulting in paralysis, and often of such mild character as not to come under the observation of any physician.

REPORTS OF CASES

Blood-specimens were obtained in the latter part of November from a number of these cases, whose clinical histories are given in abstract below. For the histories in several of these cases we are indebted to various physicians of Mason City. Other patients were not seen by any physician during their illness and the only histories available were such as could be given several weeks later by the patients and their families.

CASE 1.—*Control.*—Reported by Dr. C. M. Swale, Mason City. C. T., male, aged 48, laborer, was taken sick June 24 with a chill, fever, pains in the legs and back, stiffness of neck, some delirium. On the third day there was paralysis of both thighs and legs and both upper arms, and partial paralysis of the forearms. When last seen, Nov. 24, 1910, the lower limbs and upper arms were still paralyzed, flaccid and atrophic, but showing some improvement. This is a typical case of acute anterior poliomyelitis, included in our series as a control.

TABLE 1.—INOCULATIONS IN SERIES 1 *

Monkey No.	Serum from	Description of Case	Age	Result in Monkeys
16	Case 1 (control) ..	Frank poliomyelitis	Adult.	Has remained well.
17	Case 2	Suspected poliomyelitis with spastic paralysis.	Adult.	Has remained well.
18	Case 3	Suspected poliomyelitis without paralysis (abortive).	Adult.	Has remained well.
19	Case 4	Suspected poliomyelitis without paralysis (abortive).	Adult.	Has remained well.
20	Case 5	Suspected poliomyelitis without paralysis (abortive).	Adult.	Has remained well.
21	Case 6	Suspected poliomyelitis without paralysis (abortive).	Adult.	Has remained well.
25	Case 7 †	Suspected poliomyelitis without paralysis (abortive).	16	Paralysis all extremities on sixth day.
26	Case 8 †	Suspected poliomyelitis without paralysis (abortive).	Child.	Paralysis all extremities, trunk and neck.
22	Case 9	Suspected poliomyelitis without paralysis (abortive).	Adult.	Has remained well.
23	Case 10	Suspected poliomyelitis without paralysis (abortive).	Adult.	Has remained well.
24	Case 11 †	Suspected poliomyelitis without paralysis (abortive).	.....	Paralysis all extremities on eighth day.
27	Control JR	Normal....................	Adult.	Paralysis of hind legs tenth day, all extremities twelfth day; chloroformed.
27A	Control JR	Normal....................	Adult.	Paralysis of all extremities tenth day.

* Each monkey inoculated intracerebrally Nov. 30, 1910, with 0.5 c.c. of a mixture of 5 per cent. emulsion of fresh spinal cord (of Monkey 15) 0.5 c.c.; serum to be tested, 0.5 c.c.; fresh normal serum, 0.1 c.c. Mixtures allowed to stand one hour at 37 C. and twenty hours at 15 C. before injection. ‡ Refers to same serum in Series 2.

CASE 2.—Reported by Dr. B. F. Weston, Mason City. Mrs. W., 22, waitress, was taken sick the latter part of June, 1910, with fever and indefinite general symptoms. After several days she became paralyzed in both lower limbs. She was admitted to a hospital about one week after onset. She was said to have had, at that time, a flaccid motor paralysis of both lower extremities which, however, became spastic within a few days. When the patient was seen the latter part of July, 1910, both legs and thighs were quite spastic. No active motion was possible except of the toes and slight flexion of the left knee. Passive motion was limited to partial flexion of the thighs and slight flexion of left knee—almost none of the right knee. The patellar reflexes greatly exaggerated on both sides; ankle-clonus on right side; sensation for touch and pain was normal. Examination was otherwise negative. The patient's general health was good.

Nov. 25, 1910, the left leg could be moved, but rather awkwardly. The right leg showed little, if any, improvement. Patellar reflexes were still exaggerated, more so on the right side. There was no ankle-clonus and no atrophy.

The spasticity of the paralyzed limbs, exaggeration of reflexes and absence of atrophy in this case indicated a lesion in the upper motor segment, either in the motor cortex of the brain or in the pyramidal tracts of the cord. The case was included in our series in order to ascertain the diagnosis, since it represents a rare clinical type of poliomyelitis, the diagnosis of which has always been uncertain, and whose occurrence has been a matter of some dispute.

CASE 3.—Reported by Dr. C. E. Dakin, Mason City. H. G., a woman aged 23, nurse, was taken sick suddenly June 24, after a long walk in the hot sun, with violent occipital headache, vertigo and stiffness of the neck, causing some retraction of the head. She had chilly sensations, vomited, was extremely prostrated, and felt "crazy." Temperature was normal, pulse 80. The next day she had pains in the legs and back, with tenderness along the spine, and was very restless. There was no further vomiting; the patient was constipated. The third day she complained of cramps and a sensation of numbness in the left leg, and found, on attempting to get out of bed, that this leg was weak. These symptoms gradually improved, so that in a week the patient was able to be up with no sign of paralysis. The spine, however, remained tender for several days and sensitive to jarring. A week later she had a slight recurrence of similar symptoms, with a pharyngitis.

There was *no* elevation of the temperature at any time in this case, which was seen daily by the attending physician. The patient knew of no direct association with cases of poliomyelitis, within a month prior to her illness. She was, however, at the time of her illness living at the house of a physician who had recently attended patients who were suffering from this disease.

CASE 4.—Dr. C. E. Dakin, of Mason City, gives the following account of his own illness, the nature of which was hardly suspected at the time. He was taken sick about July 1, 1910, the onset being gradual. He lost appetite, was constipated, had a coated tongue and foul breath. He suffered from a persistent occipital headache, not relieved by treatment, and from severe pains in the upper dorsal and lumbar region. The neck was stiff, so that it was painful to bend the head forward although it could be rotated without pain. No retraction of the head was noted, but it was found that the most comfortable posture was lying on the back with the head extended over a pillow placed under the shoulders. He felt extremely nervous, irritable and inclined to worry over trifles. There was no elevation of temperature. These symptoms, which reached their height about July 7, gradually subsided within the next week, except the general nervousness and irritability, which persisted a good deal longer. During this time Dr. Dakin was not confined to bed, and continued his practice.

A child of his family had an attack of acute poliomyelitis with slight peroneal paralysis in May. Also about June 23 Dr. Dakin attended a child suffering from what was clearly an abortive attack of acute poliomyelitis.

CASE 5.—The patient, Mr. S., aged 30, merchant, in Mason City, was not seen by a physician. The history was obtained some two months later from the patient and his family. He was taken sick rather suddenly about June 19, with headache, pain in neck, back and legs. The temperature was not determined. The patient felt ill for a week or more, but was not confined to bed; thought he had the influenza. For more than a week after recovery one leg remained weak and "rheumatic." No previous association with any case of poliomyelitis was known. About three weeks later a 3-year-old son (the only child of the family) developed a typical case of poliomyelitis, resulting in paralysis of the left thigh and leg.

CASE 6.—Reported by Dr. C. E. Dakin, Mason City, who first saw the patient October 25. E. D., 45, farmer, residing about 7 miles northwest of Mason City, about Oct. 16, 1910, began to feel fleeting, neuritic pains in various parts of his body. There was no special pain, tenderness or stiffness of neck or back. A chronic indigestion became much aggravated, causing gastric distress, especially after eating. The patient lost appetite, and was constipated; the tongue was coated and breath foul. He was unusually nervous, irritable and sleepless. He improved gradually, returning to his usual state of health within two or three weeks.

TABLE 2.—INOCULATIONS IN SERIES 2 *

Monkey No.	Serum from	Description of Case	Age	Result in Monkeys
30	Control JFA ‡	Normal	Adult.	Has remained well to date.
31	Control CHL	Normal	Adult.	Paralysis and death fifth day.
32	Control WHF	Normal	Adult.	Paralysis, forelegs and neck, thirteenth day.
33	Control W ‡	Normal	Child.	Very doubtful, slight illness; sixth to twelfth day loss of appetite, nervousness, excitability, slight irregular rise of temperature.
34	Control R ‡	Normal	Child.	Very doubtful, slight illness; sixth to twelfth day; symptoms as above but less marked.
35	Case 11 †	Suspected abortive case	Child.	Has remained well to date.
36	Case 7 †	Suspected abortive case	16	Paralysis of all extremities ninth day; died ninth day.
37	Case 8 †	Suspected abortive case	Child.	Has remained well to date.

* Conditions of experiment the same as in Series 1, except that virus used was a *1 per cent.* emulsion of fresh cord (of Monkey 29). Inoculations Dec. 24, 1910. † Refers to same serum in Series 1. ‡ Refers to same serum in Series 3.

Monkey No.	Serum from	Description of Case	Age	Result in Monkeys
38	JFA (see monkey 30) ‡	Normal	Adult.	Paralysis of all extremities thirteenth day; chloroformed.
39	R (see monkey 34) ‡	Normal	Child.	Paralysis of all extremities tenth day; chloroformed.
40	W (see monkey 35) ‡	Normal	Child.	Paralysis of neck and forelegs tenth day; chloroformed

* Conditions of experiment the same as in Series 1, using a *5 per cent.* emulsion of fresh spinal cord (of Monkey 9). Inoculations Jan. 12, 1911. This series is a control on Series 1. † Refers to same serum in Series 2.

A boy living in the same house was taken sick with acute poliomyelitis Oct. 10, 1910, and died October 16. The other two members of the household remained well at this time; but, as stated in connection with Case 7, both had suffered somewhat, similar attacks about August 1.

CASE 7.—P. G., a girl aged 16, living about seven miles northwest of Mason City, was taken sick July 11 with headache, slight backache, pains in the knees, nausea and vomiting; diarrhea; fever doubtful. There was no stiffness of neck. The patient was in bed part of one day. Felt ill and unusually weak for several days thereafter.

There was no known contact with any case of poliomyelitis prior to onset. There had, however, been a considerable gathering of neighbors at this house one week prior, and the patient and other members of the family went back and forth to Mason City, where poliomyelitis prevailed at that time.

This was the first of a group of generally similar cases occurring in this and neighboring families. Other cases of similar illness occurred in this same family as follows: sister, aged 6, July 14; two sisters aged 7 and 8 respectively, July 15 or 16; brother, aged 10 (Case 8), July 22; father, aged 49 (Case 9), August 3. Two other members of the family, one adult and one aged 13, remained well.

It was stated that cases of similar illness had occurred about the same time in several neighboring families, all of which had been associated more or less closely with these cases, viz.:

Family B.—One case, adult, July 29.

Family W.—Five cases, about August 1.

Family D.—Two cases about the same time. This is the family of Patient 6. The two who were sick at this time remained well during the subsequent illness of the other members of the household.

Family M.—One case, date not known.

Family E. B.—One case, some time after August 15.

Family C. B.—Two cases (one of them Case 10), July 31.

CASE 8.—R. G., brother of Patient 7, aged 10, was ill with sudden onset about July 22; had fever, sore throat, headache, pains in neck, back and limbs; was at first restless, then drowsy. After staying in bed one day he felt better and got up, but still had pain in the back. He fell down several times this day, apparently because of weakness of the legs. The third day he felt well, except for weakness, which gradually disappeared.

CASE 9.—W. G., father of Patients 7 and 8, aged 49, farmer, first noted, August 3, while driving his wagon, that the jolting caused him pain all over. Later in the same day he had a headache, chilly sensations and fever. The pain continued all day, chiefly in the back, neck and shoulders. The patient was constipated and had no appetite. The second day his ankles felt stiff and sore, and he felt extremely weak and uncertain on his legs. After the second day he felt much better, except for the weakness, which gradually improved, leaving him in his usual health.

CASE 10.—Reported by Dr. C. E. Dakin, Mason City. C. B., aged 48, carpenter, about July 31 began to have an occipital headache, was constipated, had no appetite; felt very weak, tired and faint. He was troubled at times with vertigo, brought on by sudden turning of the head. The cervical and dorsal spine was tender. The headache and vertigo were worse when in the sunlight. There was some photophobia. The pupils were contracted and reacted sluggishly to light. Reflexes otherwise normal. These symptoms continued for about a week and for a much longer time the patient suffered from indigestion and continued to feel weak and easily tired.

The wife of this patient was taken sick about the same time with practically identical symptoms. These two had been between July 14 and 31, to a house where a child was sick at the time with a pretty definite abortive attack of poliomyelitis. One of them had also been to a house where two sisters of Patients 7 and 8 had visited while sick. A *member of the* household of Patients 7, 8 and 9 was said to be a frequent visitor at the house of Mr. B. He and his wife are the family "C. B." mentioned under Case 7.

CASE 11.—Reported by Dr. Fred Albert, Mason City. J. A., male, aged 7, residing on a farm about 5 miles northeast of Mason City, was taken sick suddenly June 30 or July 1, 1910. When seen by Dr. Albert, July 2, he had a temperature of 102.5

In Mason City, Iowa, a town of about 14,000 inhabitants, there occurred from April to September, 1910, forty cases of undoubted acute anterior poliomyelitis, resulting in typical flaccid atrophic paralysis. At the same time there occurred a considerable number of cases of illness with symptoms suggestive of the early symptoms of acute poliomyelitis, but not resulting in paralysis, and often of such mild character as not to come under the observation of any physician.

REPORTS OF CASES

Blood-specimens were obtained in the latter part of November from a number of these cases, whose clinical histories are given in abstract below. For the histories in several of these cases we are indebted to various physicians of Mason City. Other patients were not seen by any physician during their illness and the only histories available were such as could be given several weeks later by the patients and their families.

CASE 1.—*Control.*—Reported by Dr. C. M. Swale, Mason City. C. T., male, aged 48, laborer, was taken sick June 24 with a chill, fever, pains in the legs and back, stiffness of neck, some delirium. On the third day there was paralysis of both thighs and legs and both upper arms, and partial paralysis of the forearms. When last seen, Nov. 24, 1910, the lower limbs and upper arms were still paralyzed, flaccid and atrophic, but showing some improvement. This is a typical case of acute anterior poliomyelitis, included in our series as a control.

CASE 2.—Reported by Dr. B. F. Weston, Mason City. Mrs. W., 22, waitress, was taken sick the latter part of June, 1910, with fever and indefinite general symptoms. After several days she became paralyzed in both lower limbs. She was admitted to a hospital about one week after onset. She was said to have had, at that time, a flaccid motor paralysis of both lower extremities which, however, became spastic within a few days. When the patient was seen the latter part of July, 1910, both legs and thighs were quite spastic. No active motion was possible except of the toes and slight flexion of the left knee. Passive motion was limited to partial flexion of the thighs and slight flexion of left knee—almost none of the right knee. The patellar reflexes greatly exaggerated on both sides; ankle-clonus on right side; sensation for touch and pain was normal. Examination was otherwise negative. The patient's general health was good.

Nov. 25, 1910, the left leg could be moved, but rather awkwardly. The right leg showed little, if any, improvement. Patellar reflexes were still exaggerated, more so on the right side. There was no ankle-clonus and no *atrophy*.

The spasticity of the paralyzed limbs, exaggeration of reflexes and absence of atrophy in this case indicated a lesion in the upper motor segment, either in the motor cortex of the brain or in the pyramidal tracts of the cord. The case was included in our series in order to ascertain the diagnosis, since it represents a rare clinical type of poliomyelitis, the diagnosis of which has always been uncertain, and whose occurrence has been a matter of some dispute.

CASE 3.—Reported by Dr. C. E. Dakin, Mason City. H. G., a woman aged 23, nurse, was taken sick suddenly June 24, after a long walk in the hot sun, with violent occipital headache, vertigo and stiffness of the neck, causing some retraction of the head. She had chilly sensations, vomited, was extremely prostrated, and felt "crazy." Temperature was normal, pulse 80. The next day she had pains in the legs and back, with tenderness along the spine, and was very restless. There was no further vomiting; the patient was constipated. The third day she complained of cramps and a sensation of numbness in the left leg, and found, on attempting to get out of bed, that this leg was weak. These symptoms gradually improved, so that in a week the patient was able to be up with no sign of paralysis. The spine, however, remained tender for several days and sensitive to jarring. A week later she had a slight recurrence o similar symptoms, with a pharyngitis.

There was no elevation of the temperature at any time i this case, which was seen daily by the attending physician The patient knew of no direct association with cases of poliomyelitis, within a month prior to her illness. She was, however, at the time of her illness living at the house of a physician who had recently attended patients who were sufferin from this disease.

CASE 4.—Dr. C. E. Dakin, of Mason City, gives the followin account of his own illness, the nature of which was hardl suspected at the time. He was taken sick about July 1, 1910 the onset being gradual. He lost appetite, was constipated had a coated tongue and foul breath. He suffered from a persistent occipital headache, not relieved by treatment, and fron severe pains in the upper dorsal and lumbar region. The necl was stiff, so that it was painful to bend the head forwar although it could be rotated without pain. No retraction o the head was noted, but it was found that the most comfortabl posture was lying on the back with the head extended ove pillow placed under the shoulders. He felt extremely nervou irritable and inclined to worry over trifles. There was no elevation of temperature. These symptoms, which reached thei height about July 7, gradually subsided within the next week except the general nervousness and irritability, which persisted a good deal longer. During this time Dr. Dakin wa *not confined to bed, and continued his practice.*

A child of his family had an attack of acute poliomyelitis with slight peroneal paralysis in May. Also about June 23 Dr. Dakin attended a child suffering from what was clearly an abortive attack of acute poliomyelitis.

Case 5.—The patient, Mr. S., aged 30, merchant, in Mason City, was not seen by a physician. The history was obtained some two months later from the patient and his family. He was taken sick rather suddenly about June 19, with headache, pain in neck, back and legs. The temperature was not determined. The patient felt ill for a week or more, but was not confined to bed; thought he had the influenza. For more than a week after recovery one leg remained weak and "rheumatic." No previous association with any case of poliomyelitis was known. About three weeks later a 3-year-old son (the only child of the family) developed a typical case of poliomyelitis, resulting in paralysis of the left thigh and leg.

Case 6.—Reported by Dr. C. E. Dakin, Mason City, who first saw the patient October 25. E. D., 45, farmer, residing about 7 miles northwest of Mason City, about Oct. 16, 1910, began to feel fleeting, neuritic pains in various parts of his body. There was no special pain, tenderness or stiffness of neck or back. A chronic indigestion became much aggravated, causing gastric distress, especially after eating. The patient lost appetite, and was constipated; the tongue was coated and breath foul. He was unusually nervous, irritable and sleepless. He improved gradually, returning to his usual state of health within two or three weeks.

TABLE 2.—INOCULATIONS IN SERIES 2 *

Monkey No.	Serum from	Description of Case	Age	Result in Monkeys
30	Control JFA ‡	Normal....................	Adult.	Has remained well to date.
31	Control CHL	Normal....................	Adult.	Paralysis and death fifth day.
32	Control WHF	Normal....................	Adult.	Paralysis, forelegs and neck, thirteenth day.
33	Control W ‡	Normal....................	Child.	Very doubtful, slight illness; sixth to twelfth day loss of appetite, nervousness, excitability, slight irregular rise of temperature.
34	Control R ‡	Normal....................	Child.	Very doubtful, slight illness; sixth to twelfth day; symptoms as above but less marked.
35	Case 11 †	Suspected abortive case.....	Child.	Has remained well to date.
36	Case 7 †	Suspected abortive case.....	16	Paralysis of all extremities ninth day; died ninth day.
37	Case 8 †	Suspected abortive case.....	Child.	Has remained well to date.

* Conditions of experiment the same as in Series 1, except that virus used was a *1 per cent.* emulsion of fresh cord (of Monkey 29). Inoculations Dec. 24, 1910. † Refers to same serum in Series 1. ‡ Refers to same serum in Series 3.

TABLE 3.—INOCULATIONS IN SERIES 3 *

Monkey No.	Serum from	Description of Case	Age	Result in Monkeys
38	JFA (see monkey 30) ‡	Normal....................	Adult.	Paralysis of all extremities thirteenth day; chloroformed.
39	R (see monkey 34) ‡	Normal....................	Child.	Paralysis of all extremities tenth day; chloroformed.
40	W (see monkey 35) ‡	Normal....................	Child.	Paralysis of neck and forelegs tenth day; chloroformed

* Conditions of experiment the same as in Series 1, using a *5 per cent.* emulsion of fresh spinal cord (of Monkey 9). Inoculations Jan. 12, 1911. This series is a control on Series 1. † Refers to same serum in Series 2.

A boy living in the same house was taken sick with acute poliomyelitis Oct. 10, 1910, and died October 16. The other two members of the household remained well at this time; but, as stated in connection with Case 7, both had suffered somewhat similar attacks about August 1.

Case 7.—P. G., a girl aged 16, living about seven miles northwest of Mason City, was taken sick July 11 with headache, slight backache, pains in the knees, nausea and vomiting; diarrhea; fever doubtful. There was no stiffness of neck. The patient was in bed part of one day. Felt ill and unusually weak for several days thereafter.

There was no known contact with any case of poliomyelitis prior to onset. There had, however, been a considerable gathering of neighbors at this house one week prior, and the patient and other members of the family went back and forth to Mason City, where poliomyelitis prevailed at that time.

This was the first of a group of generally similar cases occurring in this and neighboring families. Other cases of similar illness occurred in this same family as follows: sister, aged 6, July 14; two sisters aged 7 and 8 respectively, July 15 or 16; brother, aged 10 (Case 8), July 22; father, aged 49 (Case 9), August 3. Two other members of the family, one adult and one aged 13, remained well.

It was stated that cases of similar illness had occurred about the same time in several neighboring families, all of which had been associated more or less closely with these cases, viz.:

Family B.—One case, adult, July 29.

Family W.—Five cases, about August 1.

Family D.—Two cases about the same time. This is the family of Patient 6. The two who were sick at this time remained well during the subsequent illness of the other members of the household.

Family M.—One case, date not known.

Family E. B.—One case, some time after August 15.

Family C. B.—Two cases (one of them Case 10), July 31.

Case 8.—R. G., brother of Patient 7, aged 10, was ill with sudden onset about July 22; had fever, sore throat, headache, pains in neck, back and limbs; was at first restless, then drowsy. After staying in bed one day he felt better and got up, but still had pain in the back. He fell down several times this day, apparently because of weakness of the legs. The third day he felt well, except for weakness, which gradually disappeared.

Case 9.—W. G., father of Patients 7 and 8, aged 49, farmer, first noted, August 3, while driving his wagon, that the jolting caused him pain all over. Later in the same day he had a headache, chilly sensations and fever. The pain continued all day, chiefly in the back, neck and shoulders. The patient was constipated and had no appetite. The second day his ankles felt stiff and sore, and he felt extremely weak and uncertain on his legs. After the second day he felt much better, except for the weakness, which gradually improved, leaving him in his usual health.

Case 10.—Reported by Dr. C. E. Dakin, Mason City. C. B., aged 48, carpenter, about July 31 began to have an occipital headache, was constipated, had no appetite; felt very weak, tired and faint. He was troubled at times with vertigo, brought on by sudden turning of the head. The cervical and dorsal spine was tender. The headache and vertigo were worse when in the sunlight. There was some photophobia. The pupils were contracted and reacted sluggishly to light. Reflexes otherwise normal. These symptoms continued for about a week and for a much longer time the patient suffered from indigestion and continued to feel weak and easily tired.

The wife of this patient was taken sick about the same time with practically identical symptoms. These two had been between July 14 and 31, to a house where a child was sick at the time with a pretty definite abortive attack of poliomyelitis. One of them had also been to a house where two sisters of Patients 7 and 8 had visited while sick. A member of the household of Patients 7, 8 and 9 was said to be a frequent visitor at the house of Mr. B. He and his wife are the family "C. B." mentioned under Case 7.

Case 11.—Reported by Dr. Fred Albert, Mason City. J. A., male, aged 7, residing on a farm about 5 miles northeast of Mason City, was taken sick suddenly June 30 or July 1, 1910. When seen by Dr. Albert, July 2, he had a temperature of 102.5

F., had a severe occipital headache, pain and tenderness of the spine, and some inflammation of the tonsils. The next day the temperature was normal and the headache and pain and tenderness of the spine had disappeared.

Two other children in the same house were taken sick between June 29 and July 1 with similar symptoms. One recovered within a few days, while the other developed typical poliomyelitic paralysis of the arms.

Cases 3 to 11 inclusive are representative of a class of cases which were reported to be quite common in and around Mason City during the epidemic of poliomyelitis. While there is a considerable variety in their symptomatology there is, in most cases, a fairly distinct syndrome, viz., headache, more commonly occipital; pain and tenderness along the spine; neuritic pains and hyperesthesia of the limbs; a marked degree of restlessness or irritability; prostration out of proportion to the severity of the other symptoms; some gastro-intestinal derangement (anorexia, nausea, constipation or diarrhea); occasionally other symptoms of nervous derangement, as vertigo, photophobia, delirium, muscular paresis, disordered reflexes. The temperature was definitely determined to be normal in Cases 3, 4 and 10, and found elevated (102.5° F.) in Case 11. In the rest of the cases no exact information is available, as the patients were not under the observation of a physician during the acute stage. Dr. Dakin,[8] of Mason City, who has reported elsewhere 36 cases of poliomyelitis, including Cases 3 and 10 of the above series, describes, as very characteristic, a staring, terror-stricken facial expression, which he noted also in Cases 3, 6 and 10 of our series.

Blood-specimens were obtained from all these cases by venepuncture during the latter part of November. The serum was withdrawn after coagulation and kept in closely stoppered sterile bottles. Repeated tests showed all specimens of serum to be sterile when used.

The virus used was originally obtained from the Rockefeller Institute for Medical Research through the courtesy of the director, Dr. Simon Flexner. It had been propagated through a long series of monkeys at the Rockefeller Institute and found very uniformly virulent. We have found it virulent for all the fresh monkeys which we have inoculated other than those mentioned in the following series.

SERIES 1.—Monkey 15, inoculated with the above virus, developed complete paralysis of the hind legs on the seventh day; it was chloroformed and necropsy performed the same day. A 5 per cent. emulsion of the fresh spinal cord was prepared in normal salt solution, and filtered through paper to remove gross particles. One-half cubic centimeter of this emulsion was added to an equal amount (0.5 c.c.) of each of the serums to be tested.

To each mixture was added 0.1 c.c. of fresh normal human serum (J. R.). As controls, two mixtures were made with normal human serum (J. R.). The mixtures of serum and virus were kept 1 hour at 37 C., then placed over night (about 20 hours) at 15 C. A series of monkeys was inoculated in the brain, each monkey receiving 0.5 c.c. of one of the mixtures of virus and serum, Nov. 30, 1910.

The two control monkeys receiving the mixtures of normal serum and virus developed typical paralysis on the eighth and tenth days respectively.

The monkeys receiving the mixtures of virus with the serum of Patients 7, 8 and 11 also developed equally typical paralysis on the seventh, fifth and seventh days respectively. All the others have remained well up to the present time (Feb. 4, 1911).

It will be noted that the three specimens of serum which failed to affect the virus were from young persons (Patient 7, aged 16; Patient 8, aged 10; Patient 11, aged 7). The remainder of the serums were from adults. This suggested two possibilities:

1. The serum of normal adults may have considerable germicidal properties for the virus.

2. The serum of children, even when they have had an attack of poliomyelitis, may not develop germicidal antibodies; or may develop them in smaller amounts than the serum of adults.

SERIES 2.—To test these hypotheses, we inoculated another series of monkeys with exactly the same technic, except that, instead of a *5 per cent.* emulsion of spinal cord we used a *1 per cent.* emulsion (fresh cord of Monkey 29, inoculated December 13; paralysis of hind legs December 23; chloroformed and cord removed December 23).

In this series we used again the serum of Patients 7, 8 and 11, and for controls took the serum of three normal adults (J. F. A., C. H. L., and W. H. F.) and of two normal children (R. and W.). Granting an equal concentration of the virus in the two cords used in series 1 and 2 (Monkey 15 and Monkey 29), each specimen of serum would now be mixed with the same *volume* of emulsion as in Series 1, but with *one-fifth of the amount of virus.* Also, the amount used in inoculation (0.5 c.c.) would represent only one-fifth of the amount of virus inoculated into the animals of series 1.

The results in this series were somewhat irregular. The monkeys receiving the serum of two of the normal adults (C. H. L. and W. H. F.) developed poliomyelitis on the fifth and thirteenth days respectively. The monkey which received the serum of Patient 7 developed paralysis of all extremities on the eighth day. None of the other monkeys, including those which received the serum of Patients 8 and 11, the serum of one normal adult (J. F. A.), and of the two normal children, have developed paralysis up to this time. Two of the monkeys, however (those receiving the serum of the two normal children), appeared about a week after inoculation to have an indefinite illness, manifested by slight rises of temperature, loss of appetite, nervousness, and undue excitability. Whether these may be considered abortive attacks of poliomyelitis is extremely questionable.

These results would indicate that in this series we had approached the limit of proportions in which normal human serum may exert a neutralizing effect on the virus of poliomyelitis, or else had approached the minimum effective amount of virus for inoculation. They indicate pretty clearly that the serum of Patient 7 had no unusual germicidal properties, but leave the other two cases (8 and 11) in doubtful status.

SERIES 3.—Three specimens of normal serum having been found capable of neutralizing the virus in the proportion used in Series 2, that is, against equal volumes of a *1 per cent.* emulsion of virus, it remained to test these three specimens again under the conditions of Series 1. Accordingly we inoculated another series of monkeys, using a *5 per cent. emulsion* of virus (fresh cord of Monkey 9, inoculated Jan. 7, 1911; died fourth day; gross and histologic lesions typical).

The serums used were the same specimens which had shown neutralizing properties in Series 2, viz., from one normal adult (J. F. A.) and two normal children (R. and W.). The technic and proportions were exactly as in Series 1.

All three monkeys came down with typical paralysis between the eighth and the twelfth days.

The three series of experiments are presented in the accompanying tables.

SUMMARY

The results of these experiments may be summarized as follows:

Normal Human Serum.—The results in Series 2 indicate that normal human serum may have a germicidal action on the virus of poliomyelitis. If this is so, however, the action has quantitative limits which clearly differentiate it from the action exercised by the serum of persons who have had poliomyelitis as shown in

---

[8] Dakin, C. E.: Iowa Med. Jour., Nov. 15, 1910, p. 229.

Series 1 and 3. No appreciable difference has been demonstrated between the normal serum of adults and of children in regard to their action on the virus.

Serum of Patients Who Have Recovered.—As shown by the workers above cited and by our results, the serum of persons who have recently recovered from frank attacks of poliomyelitis exhibits a germicidal action on the virus considerably greater than that exhibited by normal serum. Serum from a person suffering from paralysis of spastic type showed the same properties, thus confirming the clinical evidence that acute poliomyelitis may cause paralysis of this type.

The serum of six out of nine patients (66.7 per cent.) who had recently recovered from suspected poliomyelitis without paralysis (abortive cases) showed the same germicidal action as the serum from a frank case of poliomyelitis.

In the serum from the other three suspected abortive cases of poliomyelitis we were unable to demonstrate any germicidal property beyond that shown by normal serum. These three specimens of serum were all obtained from young persons. These three cases clinically resembled poliomyelitis more than did some of the adult cases; and the symptoms were, on the whole, equally severe. The following possibilities suggest themselves:

1. The cases may not have been poliomyelitis.
2. They may have been poliomyelitis, but, if so, antibodies were either formed in less amount, or disappeared more rapidly than in the adult cases.

The experimental evidence on which the specificity, constancy and quantitative relations of this reaction must be estimated is scant. So far as it goes, however, it justifies the inference that the reaction as demonstrated in our experiments is specific.

We feel justified in concluding that the diagnosis of acute poliomyelitis has been established in six of our nine suspected abortive cases. The diagnosis in the other three is not cleared up by the experiments. The clinical and epidemiologic evidence of poliomyelitis in these cases must be weighed against the absence of a serum-reaction of unknown constancy.

The facts here presented have a significant bearing on the diagnosis and epidemiology of acute anterior poliomyelitis.

DIAGNOSIS

The generally accepted criterion for diagnosis of poliomyelitis has been the development of paralysis or at least definite weakness. It has been urged that the attempt to make a diagnosis on any clinical evidence less than this would result in hopeless confusion; and this is partly true in the present state of our knowledge of the disease. In the cases of our series, however, poliomyelitis had been suspected on clinical evidence alone and confirmed by biologic test in 66.7 per cent., a fact which would indicate that the diagnosis of abortive cases of this class is not wholly a matter of guess-work, provided special attention has been directed to poliomyelitis, as was the case in Mason City. No laboratory diagnostic methods of demonstrated reliability and universal application have been evolved. The early examination of cerebrospinal fluid is the most reliable laboratory method at present known. Lumbar puncture for diagnosis is hardly justifiable, however, unless some consideration of the safety, either of the patient or of the community, makes an accurate diagnosis of special importance. Total and differential leukocyte counts offer a promising aid to diagnosis, but much more work will be necessary to establish the reliability of this method. But even in the absence of any specific diagnostic methods, much light can doubtless be thrown on the subject by a careful and conservative study of all cases which may reasonably be suspected of being cases of poliomyelitis, paying especial attention to examination of the nervous system and to association with cases of frank poliomyelitis.

Until the clinical recognition of poliomyelitis is placed on a more reliable basis there will remain an indeterminable factor in its epidemiology, a factor whose significance can only be surmised at present. Conclusions from epidemiologic data will have to be correspondingly conservative.

A more detailed discussion of abortive cases, as observed in Iowa, and of their epidemiologic relations will be reported in a forthcoming bulletin of the Hygienic Laboratory.

Therapeutics

PROPHYLAXIS OF SCARLET FEVER

Every physician, no matter how limited or specialized he may attempt to make his practice, is likely to encounter a case of scarlet fever, and to have his opinion asked in regard to what should be done to prevent the transmission of the disease to others. Even if he does not personally encounter the disease, he cannot avoid being asked the same question, apropos of some case he has not seen, by an anxious mother or a father seeking for positive information from one whom they believe to have the knowledge of an expert. It reflects no credit on his scientific attainments, it does not increase the confidence in him of his patients, if he cannot state promptly, clearly, concisely and positively what should be done by the family in which the disease occurs to prevent its spread to other individuals, what the family which does not have it, but is afraid of getting it, should themselves do, as well as what they have a right to expect others to do, in order to prevent the spread of the disease.

To the striking development of knowledge of sanitary science and preventive medicine which has taken place during the last three or four decades we are indebted for the wider recognition of the fact that scarlatina, scarlet rash and scarlet fever are synonymous terms, that they do not indicate different diseases, but one and the same disease. Formerly, many of the laity and not a few physicians believed, or at least said, that scarlatina and scarlet rash were different from scarlet fever. But numerous careful observations have shown, and the profession generally has learned, that while scarlet fever may be, and often is, a very serious disease with high temperature, severe sore throat, intense and widely spread eruption, followed by copious desquamation, the fever may be slight or entirely absent, the throat may not show more than slight congestion, the eruption, if not entirely absent, may be not very pronounced in appearance, not widely spread over the body and of rather transient duration, while the desquamation may be so slight as to be hardly recognizable.

Furthermore, it is now generally recognized not only that the very mild cases may be followed by the most serious sequelæ which are observed after the severe forms of the disease, and particularly by inflammation of the kidneys, but also that severe forms of scarlet fever may be, and often are, contracted from patients whose symptoms have been exceedingly mild.

Scarlet fever differs from measles, with which it is often associated in discussions, and in popular thought, in the fact that everyone seems to be susceptible to measles, and to contract the disease on exposure, if he has not already suffered an attack; while many seem to be not susceptible to scarlet fever, and do not contract the disease after direct and frequent exposure. A possible explanation of this apparent immunity to scarlet fever may be, at least in some cases, that these immune individuals have in their earlier life passed through an attack of scarlet fever of so mild a type that no physician was called to the patient, or if one was called, he did not recognize the nature of the disease. This, however, probably does not explain all cases of apparent immunity. Undoubtedly there are many persons who never contract the disease except after unusual exposure. On the other hand, it is unjustifiable carelessly or wittingly to expose child or adult to the disease, no matter how mild the type may be.

At the outset of a discussion of the subject we are hampered by the lack of any definite, positive knowledge as to the exact nature of the disease, and the method in which it is transmitted from one individual to another. It has long been believed that the contagious element of the disease existed in the scales which occur in greater or less profusion during desquamation. At present there is a tendency to believe that the scales do not possess great power of transmitting the disease during all stages of desquamation, and especially toward the termination of that process. On the other hand, it has not been proved that the scales are innocuous, or that they become so at any definite period of the stage of desquamation. Consequently, it becomes of great importance to control the dissemination of these scales.

Furthermore, of late the belief has been gaining ground that the element of contagion exists actively and abundantly in the secretions from the throat and nose, and also in the discharges from the ear and from suppurating glands when they are present. Obviously then, the problem which confronts both family and physician, as well as sanitarian, is to control the dissemination of these various secretions, discharges, exfoliations, and the usual excretions.

The key to the mastery of the problem is a dual one and embraces first, isolation; second, disinfection.

The establishment of isolation often taxes severely the tact and good judgment of the physician. If the family is large and lives in a small house or apartment and on a limited income, and if the municipality of which they are citizens affords the luxury of an isolation hospital, or a hospital or wards of a hospital are set apart for the treatment of contagious diseases, obviously the easiest, and, for the family, the cheapest way out of the otherwise complicated situation is to transport the patient immediately to such an institution. Here he will be under the care of attendants who are accustomed to handling patients with the disease, and who are trained to exercise all the precautions necessary to prevent the spread of the disease.

But it is possible to make this disposition of the case in only a limited number of localities. Most towns have no special provision for taking care of scarlet fever, and in such cases the patients must be treated in their own homes. If the family has ample means and lives in a large house, a large room or a suite of rooms must be set apart for the exclusive use of the patient and the special attendant, who must be secured to give hir exclusive attention. Such an apartment or suite should if possible, be selected on the third floor of the house o at the end of a hall, so that the other members of th family will have no occasion to go near it. The roor should be large and sunny, and all unnecessary articles such as curtains, upholstered furniture, and ornaments should be removed, so that there will be as few article as possible to which the disease poison may adhere an which will need to be cleaned or destroyed after th recovery of the patient. The attendant should no invade other parts of the house. Food and other necessities should be left outside the door of the apartmen occupied by the patient by another member of th household. Similarly, everything which require removal from the infected apartment should be disinfected and placed outside the apartment, and thenc carried away. The most important things which ar likely to require removal are dishes, clothing, an excreta. These should be disinfected by being placed i suitable vessels and then allowed to soak for an hour i a 2.5 per cent. solution of phenol (carbolic acid) Things which are of little or no value and which ar combustible, such as the remnants of food and pieces o cloth or paper which have been used about the roon should be burned. If the nurse finds it necessary t leave the patient's quarters, she should change all he outer garments outside of the patient's room, she shoul cover her hair, and avoid coming into close contact wit anyone. These precautions of isolation should be carried out continuously and strictly until desquamation i entirely completed. During the period of desquamatio the patient should be sponged or bathed once or twice day with hot water (and if there are bath-room facilities the convalescent should have a daily hot tub bath) and then the skin should be anointed with adeps lan hydrosus (lanolin) which has been softened with almon (or other bland) oil, and perfumed to suit. Phenc (carbolic acid) ointments are inadvisable, as any absorption would irritate the kidneys. Sponging with alcoh is contra-indicated. After desquamation has ceased, th patient should remove all the clothing which he ha been wearing, take a warm bath, with soap, and hav his head well shampooed. Then he must dress himsel throughout in fresh clothing.

After the patient has left the apartment it should b thoroughly disinfected. Formerly this was accomplished by burning sulphur in the room, but this ha been superseded by formaldehyd, which is more efficient is less injurious to the contents of the room, and is nc more troublesome nor much more expensive. Drawer of bureaus and chiffoniers should be opened and thei contents loosened, clothing should be hung on chairs o lines, and the bedding should be distributed so that th formaldehyd gas may easily penetrate everywhere. Th 40 per cent. formaldehyd solution may be efficientl used by sprinkling it on wet sheets hung on line stretched through the room. Keyholes and open space around doors and windows should be stuffed with cottor cloth, or paper, so as to retain the gas in efficient concentration to disinfect the room. One pint of the so called 40 per cent. solution should be used for a roon of ordinary size. After twenty-four hours the window of the room should be opened widely, and fresh air and sunlight should be allowed to enter freely and penetrate every part of the room. It should never be forgotten that outside air and sunshine are among the most useful of disinfectants. Carpets, rugs and bedding should be hung outdoors, so as to be thoroughly exposed to the sun and wind. Such articles of clothing and bedding as are washable should be boiled for an hour.

When it is possible to carry out such strict isolation as has been described, there is no necessity of quarantining the rest of the family, but, unfortunately, such complete isolation is ideal, and can rarely be carried out in actual practice. Even when a large family occupies a few rooms, it is essential that one room be selected for the patient, and that he be kept in it constantly, and that the other members of the family be kept out of it entirely, except one who is selected to act as the attendant, usually the mother. Under such conditions it is usually entirely impracticable for the attentant to remain constantly in the room with the patient. She must frequently leave the room, not only to get things which the patient requires, but also to perform services for the remainder of the family. Under these circumstances it is desirable and is often entirely practicable that such members of the family as attend school, or work in stores or shops should leave home, and should live elsewhere for six or eight weeks. Those who are obliged to remain at home should avoid as much as possible coming into contact with the attendant. The latter should have several aprons, with sleeves, and large enough to cover all her other clothing. One of these she should wear constantly while in the patient's room. A sheet dampened with phenol (carbolic acid) solution, or other antiseptic solution, hung over the door is believed by many to assist materially in preventing the spread of the infectious agent.

Just here a word should be said of the physician's personal duty in order to avoid carrying the disease from house to house. It is generally believed by the medical profession that physicians who use even a moderate degree of caution rarely transport the disease from a patient to another individual, and when this does happen, the victim is usually a member of his own family.

Certain precautions he may wisely observe. He should endeavor so to arrange his calls that he will not go directly from a patient ill with scarlet fever to a family in which there is a child. On entering the house of such a patient he should put on a long cotton, linen or rubber coat, which should be left just outside the patient's door. He should avoid sitting on the bed, or allowing the bed-clothing to come in contact with his own clothing. He should not prolong his visit unnecessarily. Before leaving the room he should thoroughly wash his hands and dry them on a clean towel.

During the convalescence the patient should not be allowed to use books from the public library or the public school, and should use only such books, magazines and newspapers as can be burned when he is through with them, or when the period of isolation is ended. Neither should he be allowed to write and send letters through the mail or by messenger to his friends.

Can anything be done or any medicine prescribed which will prevent the development of scarlet fever in a person who has been exposed to the disease? Although many practitioners have been in the habit of prescribing medicine designed, so they claimed, to prevent persons exposed to the disease from contracting it or developing it, candor compels the statement that no drug or any treatment is known which will accomplish this result. Although belladonna has been extensively used for this purpose, and has been believed by many to have accomplished the prevention of the disease, there is no adequate reason for believing that it has ever produced this result.

If a physician feels inclined to do something, as he is often asked to do, it is perfectly legitimate to prescribe the use of an alkaline antiseptic gargle, but with the full realization on the part of the physician, even if he does not confide the fact to the family, that he cannot, thereby prevent the disease, though he may put the pharyngeal mucous membrane in a better condition to resist the invasion of pathogenic microorganisms, and consequently to lessen the severity of the inflammatory process in the throat should the disease occur.

Although often advocated, and sometimes used, the impregnation of the atmosphere of the room with antiseptics (phenol) and aromatic oils seems to be of no value in killing the germs or in hastening recovery. Various cresol preparations are recommended for this purpose, but their value is small, and the danger of too much absorption of phenol vapor causing kidney irritation is ever present. The fraudulent assertion that ozone-producing apparatus prevents the growth and dissemination of scarlet fever germs is little less than criminal.

It should not be forgotten that dogs and cats must be excluded from all patients suffering with contagious diseases, and this is especially true of scarlet fever. The doors and windows must be screened from flies, if it is the season for them.

Fatigue and the Hours of Labor.—After stating that the human body is the most efficient machine in existence, Dr. John B. Huber in the *Scientific American*, Jan. 21, 1911, says that the best surety against accident is an alert mind in a virile body, while, on the other hand, the ideal predisposition to accident is an exhausted, rundown, devitalized human machine. There is now no question, he says, of the reality of the relation between fatigue and accidents; in Europe this has been scientifically noted for practically all forms of human activity. Bank clerks make most of their mistakes in the late afternoon; and this appears to be one of the reasons for the comparatively early closing of such institutions, since bankers have found employees' mistakes to be expensive. Everyone now knows that dire calamity results when railway men work continuously too many hours. People should understand also that physicians are not to be overworked; and that rather than this, substitutes or assistants had best be willingly accepted; men who have in their charge the keeping of human health (the most precious thing in existence) must be vouchsafed normal minds in normal bodies. The part-time method of school attendance of children is, doubtless, often unavoidable. Still it has disadvantages; and of these by no means the least is that in the afternoons the minds of children are unfairly taxed, especially when they are made to grapple with such difficult subjects as mathematics, which should be a morning study, when the minds of children are clear and fresh. One here perceives the best of all arguments —from whatever viewpoint one chooses—for the eight-hour day for all forms of labor. For some kinds of labor even eight hours is much too long. It is melancholy to observe that for many employers the prevention of fatigue accidents can be brought about only by making them very expensive. A wise corporation, however selfish, will here instinctively reduce its hours of labor; for reasons of economy, if for no other. After all, it is gratifying to note that the essential parallelism of efficiency and humanity is being increasingly appreciated throughout civilization.

CANCER IN FISH

Comparative pathology is rapidly adding much valuable material for our understanding of the biology of cancer, and we are in a fair way toward the establishment of a distinct branch of research in this direction. It certainly is of much significance that cancers, or growths which greatly resemble them, occur in all animal forms, at least in all vertebrates, and are not the unhappy heritage of the human race exclusively. We are coming to realize that not only our common domestic animals may succumb to cancer, but even the cold-blooded animals sometimes suffer the same fate. Typical malignant growths have been described in birds, reptiles, frogs, turtles, salamanders, eels, and especially in fish. Schmey,[1] who has recently reviewed the literature, has found reports of fifty-nine cases of tumors in fish, not including the large numbers of thyroid tumors described in certain epidemics in fish hatcheries.

At one time it was currently stated that cancer occurred in carnivora, but not in herbivora, which bit of evidence was eagerly seized and freely used by the vegetarians. They forgot, or at least neglected to emphasize, that cancer is a disease of mature life, and that the carnivora live to a ripe old age by cutting down the herbivora in their tender, non-cancerous youth. More abundant observation has shown that the herbivora also may become cancerous if they escape the maws of the carnivora and omnivora until late enough in life to entitle them to malignant disease. Another popular fallacy—that cancer was a disease of civilization and domestication from which wild animals did not suffer—has also been demolished. While wild animals with malignant tumors seldom come under the observation of persons competent to recognize the disease, enough cases have been described to show that free wild animals may develop cancer. Wild animals in captivity frequently show malignant tumors, a rhinoceros having recently succumbed in the Frankfort Zoological Gardens to a typical cancer of the uterus.[2]

It is the tumors in fish, however, which are just now of particular interest, because of recent observations on what have seemed to be epidemics of cancer of the thyroid arising in trout and salmon kept under rather artificial conditions in fish hatcheries. Pick and Plehn first made this condition generally known, describing epidemics in which as high as 7 per cent. of the fish developed thyroid growths. Similar epidemics have been studied in this country by Gaylord and by Marine and Lenhart. It is at once apparent that the occurrence of cancer as an epidemic in this way has an important bearing on the vital questions of the contagiousness and the possible parasitic origin of cancer, and it is desirable, therefore, to point out that the cancerous nature of these growths is by no means undisputed. Up to the present time this form of thyroid growth has been observed only in salmon and trout, apparently being peculiar to this variety of fish, just as the multiple epithelial growths of the skin are found only in the carp. The evidences of malignancy are furnished chiefly by the microscopic structure, which shows an invasion of tubules into muscle and bone adjacent to the thyroid, entirely comparable to the infiltration of tissues by cancer cells in human neoplasms; but metastases have not been found, and the behavior of the affected fish is not what one might expect in cancer.

The negative side of the question has been well presented by Marine and Lenhart,[3] who bring forward the following facts for consideration: The thyroid enlargement is found in fish kept under unfavorable conditions as to water-supply and crowding, and recovery occurs when the fish are given more freedom even in the same water, or when iodin is supplied in the water; the affected fish show nothing comparable to cancer cachexia, but are large, fat and sluggish, and probably in a condition analogous to cretinism; young fish are more affected than old fish. Furthermore, the microscopic evidence of malignancy, i. e., the invasion of muscle and bone, is not proof of the cancerous nature of the growth in fish as it would be in mammals, for the reason that in fish the thyroid is not normally enclosed within a capsule as it is in the higher animals, but consists of alveoli widely distributed in the areolar space about the ventral aorta. When the fish are kept under conditions which cause a proliferation of thyroid tissue similar to goiter in mammals, the new and enlarged alveoli cause pressure atrophy and replace surrounding structures until we have the picture which has been described as carcinoma of the thyroid. The non-malignant nature of the growth is shown by the fact that after such fish are placed in good water the hyperplasia may cease and a return to relatively normal thyroid tissue takes place. It is, of course, possible that in some cases the non-malignant goiter may become cancerous, just as it does in man, but the arguments of Marine and Lenhart that most of the supposed thyroid cancers of fish merely represent goiters seem well founded.

IMPORTANT RECENT CONTRIBUTIONS TO OUR KNOWLEDGE OF POLIOMYELITIS

Landsteiner and Popper[1] first demonstrated experimentally the infectious nature of poliomyelitis. They showed that the disease could be produced in monkeys by inoculating them with an emulsion of the cord from a child who had died of poliomyelitis. This was soon confirmed by the work of Flexner and Lewis[2] who reported that, by using the intracerebral method of inoculation, they were able to transmit the disease to monkeys in series.

Since this pioneer experimental work, much has been added to our knowledge of the experimental disease by workers in this country and in Europe, reference to most of which has been previously made in these pages. Recently there have appeared in THE JOURNAL three papers by different workers which may almost be said to be the most important contributions to our knowledge of the disease since the early work above mentioned.

Osgood and Lucas[3] show that it is possible to produce typical poliomyelitis in monkeys by the inoculation of a filtrate of the nasopharyngeal mucosa of two monkeys dying without other discoverable infections six weeks, and five and a half months, respectively, after the acute stage of the disease. They were unable to transmit the disease by inoculation of the cord from the same monkeys. From this it follows that the virus of the disease may persist in an infective condition in the nasopharyngeal mucosa of monkeys several months after the acute manifestations of the disease have ceased, but that after the same period it is not demonstrable in the brain and cord.

These observations are of the highest importance and if similar results can be obtained with the nasopharyngeal mucosa from human cases it would seem that our present ideas as to the period of infectivity in recovered cases of the disease will have to be altered. These results may also explain some obscure facts in the epidemiology of the disease.

The most important feature of the paper by Drs. Flexner and Clark,[4] of the Rockefeller Institute for Medical Research, is in regard to the use of hexamethylenamin in the treatment of the disease. This drug has been used by clinicians in the treatment of poliomyelitis and has been thought by some to be of value. Theoretically, the drug should be of benefit, as it has been shown that after its administration *per os* formaldehyd can be detected in the spinal fluid. Flexner and Clark found that if the drug be given so that it be present in the spinal fluid of a monkey and its administration be continued by mouth, injection of the virus intracerebrally resulted, in some of the animals but not in all, first, in a prolongation of the period of incubation from six or eight days to twenty-four days; and, next, in the prevention of paralysis.

The authors emphasize the importance of these observations as showing that drug control of the virus in the body is a possibility, but that the successful results reported are in inhibiting infection, but not in restraining an already established infection with the virus. Flexner and Clark also report the demonstration of immunity principles in the serum of a suspected abortive case, and the confirmation of Osgood and Lucas' work as to the persistence of the virus in the nasopharyngeal mucosa of monkeys surviving the acute stage of the disease.

The paper by Anderson and Frost,[5] of the Hygienic Laboratory, which appears in this issue, deals only with the question of abortive cases. Since the publication of Wickman's[6] monograph on epidemic poliomyelitis, clinicians have come to believe that cases of the disease occur without subsequent paralysis. The clinical evidence on which such opinion is based is as follows: In outbreaks of the disease cases are encountered showing all gradations in the degree and extent of paralysis. In the same group may be found cases resulting in lasting paralysis; cases of transient paralysis, lasting only a few weeks; other cases in which there is no definite paralysis, but merely muscular weakness of short duration; and finally cases of illness with the symptoms of a general infection accompanied by symptoms indicative of meningeal, spinal or encephalic irritation, but without definite motor disturbances.

Taking advantage of the fact reported by several observers that the serum of persons who have recovered from an attack of poliomyelitis would neutralize the virus of the disease so that when injected into monkeys infection would not take place, Anderson and Frost studied the serum from nine suspected abortive cases of poliomyelitis without paralysis and found that the serum of six (66.7 per cent.) of the nine possessed the same germicidal action against the virus as the serum from a frank case of the disease with extensive paralysis. They thus established the correctness of the clinical diagnosis by confirmation with the biologic test. They also by the demonstration of neutralizing principles in the serum confirmed the clinical diagnosis of a type of poliomyelitis with spastic paralysis.

The importance of the results reported in these three papers can hardly be estimated, but their possible bearing on the epidemiology and control of the disease is obvious. The papers, however, bring out the following points very clearly:

1. The clinical diagnosis of abortive cases of poliomyelitis is a possibility and the fact that such cases have been definitely demonstrated may explain the apparent

immunity of children in households where there are cases with frank paralysis.

2. It has been demonstrated that monkeys, after the acute stage of the disease has passed, are carriers of the infection in the nasopharyngeal mucosa; and the same thing is possible with human beings. If this is proved to be the case, efforts for the control of the disease must take into consideration such carriers. Cases of these two types add serious difficulties to the efforts for the control of poliomyelitis.

3. The results obtained in the use of hexamethylenamin in inhibiting, in a certain proportion of cases, the onset of paralysis suggests the possibility of the use of this drug in serious outbreaks of the disease as a prophylactic.

SUBACUTE INFECTIVE ENDOCARDITIS

Subacute infective endocarditis is a condition long recognizable by clinicians through certain signs and symptoms; the isolation of the infectious agent from the blood in order to clinch the diagnosis is, as yet, a method of examination too seldom used.

The disease is insidious in onset and may develop in any one of several ways. Thus, one patient may suffer from dyspnea, with or without precordial distress, general weakness, emaciation, vague pains, cough, or arthralgia; another may present a condition simulating subacute rheumatic fever and often indistinguishable from it; or a third may have fever, often unexplained by the physical examination.

Clinically, the manifestations of this type of endocardial disease may include: (1) signs of valvular disease, usually present, but occasionally lacking; (2) fever, often slight, at times high and intermittent, always irregular, with or without chills; (3) malaise, gastric disturbances, weakness and emaciation; (4) anemia, usually of marked grade, with a peculiar earthy pallor of the skin; (5) splenomegaly, ostealgia, and arthralgia, joint swellings and, as Libman has pointed out, tenderness over the gladiolus sterni.

Embolic aneurysms are common. Painful erythematous nodules—the *nodosités cutanées éphémères* of the French—are sometimes present. Petechiæ are common and hematuria is not a rare complication.

The disease is more often noted among private patients than in hospital wards. Its duration varies from two months to one and a half years and it is almost invariably fatal.

According to Horder,[1] infective endocarditis is preeminently a form of streptococcal disease "for streptococci occur in 66 per cent. of the cases." The organism isolated by him, however, was not the ordinary virulent *Streptococcus pyogenes,* but a form more nearly allied to the more saprophytic streptococci of the alimentary tract—*Streptococcus salivarius,* etc.

More recently, Rosenow,[2] and Libman and Celler[3] have studied the blood of patients with subacute infectious endocarditis and have isolated organisms the presence of which they consider of diagnostic import.

In thirty-six of the forty-three cases studied by Libman and Celler blood-cultures were made. In thirty-five of these they found atypical "endocarditis cocci" which were Gram-positive, round, ovoid or bacillary in form, occurring in clusters, in pairs or in chains, never encapsulated. These cocci are smaller than ordinary streptococci or pneumococci and grow more feebly. In the original cultures from the blood, growth was noted first after forty-eight hours, rarely as early as twenty-four hours, often not until after five or six days. On agar, a feeble translucent growth appears, adherent to the surface of the medium, a characteristic lost in subcultures. "On blood-agar plates a definite clear zone is sometimes, though rarely, seen, usually taking two to four days to develop. In transplantations this is lost. Colonies in the original plates are usually white in color, with or without a green or an opaque zone about them. In subsequent cultures on blood-plates three types of growth are seen. There may be a production of green pigment, there may be a moist white growth, or a dry, almost colorless, very slight growth." They are not dissolved by bile. About one-third of the strains ferment inulin. All strains precipitate or "whiten" serum-glucose agar.

The "endocarditis cocci" are not very pathogenic for mice, though peritonitis and endocarditis have been produced by them.

The attenuated nature of these atypical cocci—whether they be pneumococci, as Rosenow and Billings[4] regard them, or streptococci, as Libman and Celler and Schottmüller[5] class them—agrees with the course of the disease and may serve to explain several of its striking features, including: (*a*) the chronicity in many cases and the latency of the malady in others; (*b*) the slight grade or entire absence of leukocytosis often seen; (*c*) the afebrile periods which are common and the occasional absence of fever altogether; (*d*) the absence of suppuration in the infarcts; (*e*) the enormous numbers of the cocci that may be present in the blood-stream without causing grave symptoms.

These "endocarditis cocci" do not appear to be specific, though they have never been found in other conditions. The discovery of them gave rise to the hope of an antiserum or of a vaccine therapy, but so far treatment along such lines has been without favorable result. In fact, according to Rosenow, vaccine therapy may even prove harmful. Now that a more accurate knowledge of the disease has been reached, and the etiology cleared up, the dawn of a rational therapy would seem to be near.

THE TESTIMONIAL

It is reported that United States District Attorney Sims has obtained a ruling from the federal courts barring out testimonials as evidence in those cases in which the question of the curative properties of "patent medicines" are before the courts. It is gratifying to learn that the courts have at last taken a stand on this question. Week in and week out, for years past, THE JOURNAL has persistently and consistently maintained that testimonials from laymen regarding the curative value of medicine or medical appliances are intrinsically worthless and scientifically valueless. In taking this attitude, it has not been assumed that such testimonials are of necessity fraudulent in their origin. We believe that, at least during the last four or five years, a large proportion of testimonials published by "patent medicine" houses and quacks of various denominations have been genuine as documents; that is to say, a large proportion have been written in good faith by individuals who really believed, at the time they wrote these tributes, that they had received benefit from the drug or appliance whose praises they sang.

The reason for this condition of affairs is perfectly apparent to physicians, but not so evident to the public. Every physician knows that a large proportion of those who are sick, or who think they are sick, will recover whether they receive treatment or not. The average layman, however, has but little faith in the healing power of Nature, and persists in ascribing the "cure" to whatever artificial means he may have employed to bring about relief. In other words, few men without scientific training are able to discriminate between a mere relation of sequence in time and one of cause and effect. It is this very human weakness to give credit to human agencies for what rightly belongs to Nature, that is chiefly responsible for the testimonial—whether the testimonial be for a "patent medicine," for a worthless electrical device or for the various forms of "absent treatment."

No man in the United States has had a better opportunity of determining the worth, or worthlessness, of testimonials than has the assistant attorney-general to the postmaster-general, Judge R. P. Goodwin. On Judge Goodwin, for some years past, has devolved the onerous task of passing on the evidence submitted by post-office inspectors in the numberless cases of fraud perpetrated on the public by various promoters, especially by nostrum vendors and quacks. Judge Goodwin's reports have been very largely the basis on which the postmaster-general has issued the fraud orders in such cases. This is what Judge Goodwin says regarding testimonials:

> "Speaking generally, it may be said that in all my experience in this office never has a medical concern, no matter how fraudulent its methods or worthless its treatment, been unable to produce an almost unlimited number of these so-called testimonial letters."

It is rather surprising that testimonials have not been debarred as evidence long ago.

Current Comment

MORE DONATIONS FOR MEDICAL EDUCATION

It is pleasing to note that no one section of the country is receiving all of the gifts and appropriations for the improvement of medical education. From Oregon comes a report that the legislature has appropriated $30,000 for the department of medicine of the University of Oregon, to be used for the improvement of the college building, for laboratory equipment and for current expenses. In addition, the regents of the university have made an appropriation from the general funds of the university to pay the salaries of full-time professors in anatomy and physiology. From Tennessee comes a report that Vanderbilt University has just received a donation of $300,000, half of which came from the General Education Board as an addition to the endowment fund of the university; the remainder was a special donation from Mr. W. K. Vanderbilt for the purchase of the campus of Peabody Normal College, a sixteen-acre tract containing five or six buildings. These buildings are to be rearranged for the medical and dental departments of the university. The receipt of this money has made it possible for Vanderbilt University hereafter to assume full responsibility, financially and otherwise, for its medical department, and steps are now being taken to establish a university hospital. These developments in the extreme Northwest and in the South not only guarantee the continuance of medical education at the universities named, but also provide stronger and better-equipped medical colleges in sections of the country where, at the present time, their influence on educational standards will be particularly helpful.

NATIONAL TUBERCULOSIS DAY

The observance of National Tuberculosis Day in the churches all over the country on or about April 30 will be similar to that of Tuberculosis Sunday last year. This plan has been arranged by the National Association for the Study and Prevention of Tuberculosis. Instead of asking that the churches give the tuberculosis cause a special Sunday service, at which the subject of tuberculosis and its prevention can be discussed, it is requested that this service be held either on April 30 or on any day near that date. The idea is to have the subject discussed in all the churches at about the same time. The national association is attempting to arouse the churches to take further interest in the subject by soliciting their cooperation in the collection of statistics on tuberculosis. It has planned to distribute from the national office and from the headquarters of the 450 state or local antituberculosis associations millions of circulars. It is stated that the national association will, also, during the next three months, display on bill-boards throughout the country 20,000 educational posters. Free space on bill-boards in many parts of the country has been donated, as well as the printing of the posters. The posters show how fresh air, good food and rest cure tuberculosis; how bad air, overwork and closed windows lead to tuberculosis; and how the careless consumptive menaces the health of his family by his careless habits.

REAL TALENT WASTED IN A NARROW FIELD

A country dairyman in Louisiana has given indications that he possesses talent of an order that seems to be in great demand among many modern business organizations. A law prohibiting the sale of watered milk threatened to interfere seriously with the vested rights, customs and emoluments of an ancient and honorable business. The canny dairyman at once surmounted the difficulty by a ruse that would delight the heart of a modern trust lawyer. "Surely they can't prevent me from selling people what they want," said he, and so when his attention was called to his little oversight in not complying with the law he answered that he sold pure milk to the customers who requested pure milk and charged them forty cents a gallon for it, but to those who preferred watered milk he sold a fluid (percentage of H_2O not stated) for which he charged twenty-five cents a gallon. Could anything be simpler? Was anyone cheated? Not according to the philosophy of our friend the dairyman who, like the Irish gentleman, probably thought, "What's the law, betune frinds, anyway?" The state board of health, however, will proceed with the prosecution.

PUCK ON ANIMAL EXPERIMENTS

Not all comic papers are silly, neither are all editors of such papers devoid of logic and common sense. After the unfair and ignorant diatribes of *Life* on animal experimentation, the cartoon in last week's issue of *Puck* is distinctly encouraging and refreshing. The artist has portrayed a venerable scientist standing by his laboratory table, on which is strapped a rabbit. The assistant, with ether cone in hand, is ready to administer the merciful anesthetic. On the one hand a crowd of sentimental antivivisectionists, well-fed, well-clothed and healthy, are crying "For Mercy's Sake, Stop!" On the other hand, a shadowy throng of sufferers, the maimed, the crippled, the sick and the dying are groaning "For Humanity's Sake, Go On!" The scientist, looking from one to the other, is evidently weighing in his mind the arguments for and against animal experimentation. *Puck's* cartoon, making an appeal to the reason and the intellect, is a distinct contrast to the frantic efforts of *Life,* which have appealed only to the ignorant, the emotional and the sentimental. In behalf of suffering humanity, we extend our thanks to *Puck.* May his shadow (and his circulation) never grow less.

Eyestrain and Neurasthenia.—The man or woman who leads a life of mental ease and muscular exercise, or the one who has a well-balanced nervous system, or a large reserve of vital energy, will probably withstand a nerve waste which in another individual leads to neurasthenic symptoms. It is possible that in the ages when the simple life was the rule, peripheral irritation and nerve waste, such as eyestrain produces, made little or no impression on the individual; but who can doubt its bad effect in this twentieth century of turmoil and worry?—E. Clarke in the *Practitioner.*

Medical News

ARKANSAS

Report of Sanatorium.—The new Arkansas Tuberculosis Sanatorium, Fayetteville, is practically full. The limit of the accommodation is seventy-four, after which patients can be received only when vacancies occur.

Elections.—At the annual meeting of the Sebastian County Medical Society, held in Fort Smith, Dr. John C. Amis was elected president; Dr. Samuel J. Ozment, vice-president; Dr. Clark S. Wood, secretary; Dr. Charles W. Garrison, treasurer, and Dr. St. Cloud Cooper, censor, all of Fort Smith.——Washington County Medical Society has elected the following officers: president, Dr. P. L. Hathcock, Lincoln; vice-president, Dr. Andrew J. Harrison, Spring Valley; secretary, Dr. Nina V Hardin, Fayetteville; treasurer, Dr. Andrew S. Gregg, Fayetteville, delegate to the state society, Dr. Thomas W. Blackburn, Canehill, and alternate, Dr. Edward F. Ellis, Fayetteville.——At the annual meeting of Greene County Medical Society, held in Paragould, January 5, the following officers were elected: president, Dr. Jones H Lamb, Beech Grove; vice-presidents, Drs. E. L. Kennedy Marmaduke; George T. Hopkins, Paragould; Felix M. Scott, Paragould; secretary-treasurer, Dr Olive A. C. Wilson, Paragould; censors, Drs. Henry N Dickson, Paragould; W. R. Owens, Paragould, and R Edward Bradsher, Marmaduke, delegate to the state society, Dr. Thaddeus Cothren, Walcott, and alternates, Dr. George T. Hopkins, Paragould, and R. Edward Bradsher, Marmaduke.——Phillips County Medical Society, at its annual meeting in Helena, elected the following officers: president, Dr. Labrun Hall, Turner; vice-president, Dr. Albert A. Hornor, Helena; secretary-treasurer, Dr. M. Fink, Helena; censors, Dr. William C. King and James B. Ellis, Helena; delegate to the state society, Dr. J W. Price, Marvell.

CALIFORNIA

Warrants Issued for Chinese Doctors.—Fourteen local Chinese practitioners of Los Angeles, charged with practicing medicine without a state license, were served with warrants, January 31. The charges were preferred by the special agent of the state medical society.

Society Meeting.—At the annual meeting of Santa Barbara County Medical Society, held January 16, the following officers were elected: president, Dr. Benjamin Bakewell, Santa Barbara; vice-presidents, Drs. William B. Cunnane, Santa Barbara; C. C. Park, Santa Barbara, and William T. Lucas, Santa Maria; secretary-treasurer, Dr. Thomas A. Stoddard, Santa Barbara.

COLORADO

Hospital Completed.—The east wing of the Denver County Hospital has been completed at a cost of $103,496.

Open-Air Rooms for School Building.—An open-air room will be constructed for the use of children suffering from tuberculosis in all new school buildings of Denver, and in all additions to existing school buildings.

School for Defective Children.—The board of education of Denver has assigned one of the school buildings for the especial use of pupils, who, for any reason, are three grades behind children of corresponding age. A relatively large number of teachers, and those of special qualifications, will be assigned to this school, which will receive pupils from any part of the county.

Nominated for State Board.—Governor Shaffroth, at an executive session of the senate, submitted the names of Dr. Sherman Williams, Denver, and Jacob C. Chipman, Sterling, and Mr. E. F. Trunk, a druggist of Denver, as members of the State Board of Health.——It is announced that the legislative committee of the state medical society will go before the committees on apportionment of both the house and senate and file objections to the appointment of Mr. Trunk as a member of the board. He is said to be willing to retire from the board on his appointment as pure food commissioner.

DELAWARE

Resident Physician Cleared.—After the investigation into the alleged death of two patients of the Delaware Hospital from poisoning by the administration of bichlorid of mercury instead of calomel, it was found that there was no trace of poison in the stomachs of the deceased, and a verdict was rendered that the deaths were due to natural causes.

Personal.—Dr. Henry W. Briggs, Wilmington, has succeeded Dr. Joseph W. Bastian, resigned, as coroner's physician.——At the annual meeting of the Physicians and Surgeons Hospital, Wilmington, January 10, Dr. Joseph P. Pyle was elected president; Dr. Josephine W. DeLacour, vice-president; Dr. Thomas H. Phillips, secretary, and Dr. Smith Cooper, treasurer.

Society Meeting.—At the annual meeting of the New Castle County Medical Society, held in Wilmington, the following officers were elected: president, Dr. Henry W. Briggs; vice-president, Dr. James A. Draper; secretary, Dr. Albert Robin; treasurer, Dr. William H. Kraemer, all of Wilmington, and delegates to the state medical society, Drs. Harold L. Springer, Wilmington, Francis L. Springer, Newport; Henry W. Briggs, William H. Kraemer, Frank Belville, Delaware City, and Henry J. Stubbs, Wilmington.

GEORGIA

State Sanatorium to Open.—It is announced that the State Tuberculosis Sanatorium, Alto, will be opened March 1. A sufficient number of applications have already been received to more than half fill the institution. Dr. Edson W. Glidden, formerly of Wallingford, Conn., is superintendent of the sanatorium.

New Medical Association Organized.—The Jefferson County Medical Association was organized at Louisville, February 7, with the aid of Dr. Wyman W. Pilcher, Warrenton, councilor of the state medical association. Dr. James W. Pilcher, Stellarville, was elected president; Dr. G. F. Carpenter, Wrens, secretary; Dr. Pierce Hubert, Louisville, delegate to the state association, and Dr. Joshua R. Beall, Blythe, delegate to the Tenth District Medical Association.

ILLINOIS

Personal.—Dr. Guy G. Dowdall, Chicago, has been appointed chief surgeon of the Illinois Central System, vice Dr. John E. Owens.——Dr. William H. Holmes, Springfield, state bacteriologist, has resigned to enter the service of the State Board of Administration as assistant physician at the Kankakee State Hospital.——Dr. Dallas B. Phemister, Chicago, has returned from Europe.

Meeting of Medical Historians.—The third meeting of the Society of Medical History of Chicago was held February 24, when Dr. Otho B. Will, Peoria, the guest of honor, delivered an address on "A Chapter on the Pioneer Period of Medicine in Illinois." Preceding the meeting there was an informal exhibition of autographic material, participated in by many members of the society.

For a Fifth, a Clinical, Year.—Senate Bill 235, introduced February 23 at the instance of the State Board of Health, provides that when a medical college has a five years' course, the fifth year clinical, its students may be admitted to examination at the end of the fourth year and, if they pass, may receive a limited license good for eighteen months, entitling them to practice in a hospital. On graduation, the student will receive a permanent license without further examination. The bill also aims to give the State Board of Health jurisdiction, in the matter of revocation of certificates, over all issued since 1877.

KANSAS

Elections.—At the biennial meeting of the Northwest Kansas Medical Society, held in Topeka, February 9, Dr. Mervin T. Sudler, Lawrence, was elected president; Dr. E. James Blair, Lawrence, vice-president; Dr. Louis V. Sams, Topeka, secretary-treasurer.——Leavenworth County Medical Society, at its annual meeting elected the following officers: Dr. Harley J. Stacey, president; Dr. Charles J. McGee, vice-president; Dr. Jacob L. Everhardy, secretary-treasurer, and Dr. J. Waldo Risdon, delegate to the state medical society, all of Leavenworth.——Harvey County Medical Society, at its annual meeting in Newton, elected Dr. Richard S. Haury, president; Dr. Max Miller, vice-president, and Dr. Frank L. Abbey, secretary-treasurer, all of Newton.

KENTUCKY

More Money for Hazelwood.—The subscription fund to provide quarters for more patients at the Association Sanatorium, Hazelwood, near Louisville, has been growing steadily, and now amounts to more than $10,000. The fund has already permitted the erection of one additional building.

District Nurses Work.—The district nurse work of the King's Daughters in their quarterly report shows 2,487 visits made to various Louisville families in the three months ended January 31. A new feature of the work recently inaugurated is the attendance of one of the district nurses on the session of the Juvenile Court on each Friday. During the past three months the children of this court have been given medical attention.

Tuberculous School Children.—Superintendent E. O. Holland of the Louisville public schools, is compiling statistics as to the number of school children suffering from tuberculosis and the number that are truant and subnormal, with a view of segregating them from other pupils. From reports he has already received from principals and teachers it is believed that such large numbers will be found in the public schools that several buildings will have to be provided for them. Twenty-five suspected cases of tuberculosis have been reported from two buildings alone. To overcome the crowding of some schools a number of grades have been assigned for afternoon study. He reports that forty of the fifty-six buildings of the city are not properly ventilated, and that in many of the buildings two pupils sit in a seat made for one. It is proposed to stimulate the mental activity of the abnormal pupils with the kind of manual training work that will most fit their individual needs. The method of dealing with the truant and semi-incorrigible pupils has not yet been determined, but it has been agreed by the Board of Education that something must be done to segregate them from other children.

LOUISIANA

Hookworm at State University.—Following the investigation made by Dr. A. S. J. Hyde, of the Hookworm Commission, it is announced that 25 per cent. of the students thus far examined at the state university are infected with hookworm.

New Hospital Opened.—The formal opening of the Presbyterian Hospital, New Orleans, occurred February 4. Addresses were made by the mayor, the president of the board of managers, the president of the parish medical society, and others. The free clinic of the hospital is located at 730 Baronne Street, and is open to the worthy poor, irrespective of religious denomination, not only by day but from 7 to 9 p. m.

Parish Society Meeting.—At the annual meeting of the Iberville Parish Medical Society, held in Plaquemine, January 31, the following officers were elected: president, Dr. Boote O. LeBlanc, Saint Gabriel; vice-president, Dr. G. A. Darcantel, Whitecastle; secretary-treasurer, Dr. Adrian A. Landry, Plaquemine; censors, Drs. Arthur A. Allain, Bayou Goula, and Rome Martinez; delegate to the state medical society, Dr. W. Glendower Owen, White Castle.

MARYLAND

Make Appropriation for Sewers.—The citizens of Easton have voted to spend $40,000 for sewerage and drainage system.

Personal.—Dr. Richard C. Massenburg, Towson, has entirely recovered from his recent illness.——Dr. Josephine A. Wright, assistant superintendent of the Eudowood Sanatorium for Consumptives, near Baltimore, has resigned and will practice in Towson.

Diphtheria in Johns Hopkins Hospital.—On account of an outbreak of diphtheria among patients, nurses and physicians in Johns Hopkins Hospital, where about 35 cases are reported, the public wards have been closed to students and the public, and the medical school has also been officially closed until further orders. Those affected have been isolated in the two wards where the first cases occurred.

Academic Day Exercises.—At the Academic Day Exercises of Johns Hopkins University, February 23, Hon. James Bryce, ambassador from Great Britain, the chief speaker, was given the degree of LL.D., and a portrait medallion of Dr. William H. Welch by Brenn of New York, and an oil painting of Dr. William H. Howell were exhibited and presented during the exercises. The Homewood Fund for the removal of the university to a new site in the suburbs now amounts to $1,200,000.

Banquet to Professor Howell.—Dr. William H. Howell of Johns Hopkins Medical School, was the guest of honor at a banquet, February 20, when a portrait of him by Cecilia Beaux, was presented to the university by Dr. Reid Hunt of Washington, and was accepted by the presiding officer, President Ira Remsen of the university. Dr. William H. Welch spoke of the valuable work done by Dr. Howell; Hon. John C. Rose, judge of the United States circuit court, spoke of him as a citizen; and Drs. Samuel J. Meltzer, New York City, and W. W. Willoughby on his work as a teacher. President Remsen stated that he had never done anything more important for the school than when he persuaded Dr. Howell, who had been offered an important position in another university, to remain with his alma mater.

Baltimore

Members of Advisory Council.—The following have been elected medical representatives of the Alumni Advisory Council of the University of Maryland: Drs. Charles E. Sadtler, Joseph W. Holland, Harry Adler, B. Merrill Hopkinson, Eugene F. Cordell, Nathan Winslow, Albert L. Wilkinson, J. Clement Clark, and James D. Iglehart.

Personal.—Dr. Henry M. Hurd has resigned the superintendency of Johns Hopkins Hospital, after having served twenty-two years. He will remain as secretary and advisor of the board of trustees. Dr. Winford H. Smith, general medical superintendent of Bellevue and Allied Hospitals, New York City, has been elected as Dr. Hurd's successor.——Dr. Summerfield B. Bond is ill in University Hospital with carcinoma of the liver and pancreas.——Dr. J. Hall Pleasants has been elected a member of the Alumni Council of Johns Hopkins University.

MASSACHUSETTS

Influenza in Worcester.—During January, it is stated that approximately 3,000 cases of epidemic influenza were reported in Worcester, with one death.

Personal.—Dr. Owen Copp, Boston, executive officer of the State Board of Insanity for twelve years, has resigned to assume charge of the Pennsylvania Hospital for the Insane, Philadelphia.——Dr. Alfred O. Hitchcock, chairman of the board of health, Fitchburg, has resigned and his duties have been temporarly assumed by Dr. Dwight S. Woodworth.——Dr. Paul Carson, port physician at Boston, has been placed in charge of the city health department's division of child hygiene and school medical inspection. Dr. William M. Gay, assistant port physician, is in temporary charge of the quarantine station.

Dental Dispensary for Children.—The Forsyth Dispensary for Children, incorporated last year by special act of the Massachusetts Legislature, is to be located at Hemenway Street near Huntington Ave., Boston, and will be one of the notable group of buildings which includes Harvard Medical School. The land, building, and a maintenance fund of $1,000,000 are the gift of John Hamilton and Thomas Alexander Forsyth in memory of their brothers, James Bennett and Thomas Henry Forsyth. The site on the Fenway consists of 51,000 square feet. The building is to be three stories and two partial mezzanine floors in height. The basement will be occupied by the general waiting room for children, janitor's rooms, boiler and engine rooms, etc.; the first floor will have a lecture room seating 250, which is intended to be used for popular lectures on dental hygiene; a room for visiting dentists, museum and research laboratory, and founders' room, and rooms for anesthesia and extracting, with male and female wards. The second floor will be used entirely for the infirmary, about which as a nucleus and subservient to the requirements of which the rest of the building is constructed. There will be in this infirmary accommodation for 108 operating chairs with waiting, *x*-ray and reserve rooms.

MINNESOTA

New Hospital.—Plans have been completed for the hospital building which Dr. George G. Eitel is to build at Fourteenth and Willow Street, Minneapolis. The building is to be five stories in height with high basement and is expected to cost $150,000.

Medical Society Meetings.—The Rice County Medical Association, at its annual meeting, held in Northfield, elected the following officers: president, Dr. Arthur C. Rogers, Faribault (reelected); vice-presidents, Drs. Warren Wilson, Northfield, and William H. Rumpf, Faribault; secretary-treasurer, Dr. Frederick U. Davis, Faribault; delegate to the state society, Dr. David M. Strang, Northfield; and alternate, Dr. Isaac F. Seeley, Northfield.——Waseca County Medical Society, at its annual meeting, elected the following officers: president, Dr. Alexander J. Rudolf, Waseca; vice-president, Dr. William M. Cory, Waterville; secretary-treasurer, Dr. Henry G. Blanchard, Waseca; censors, Drs. Frederick A. Swartwood, Waseca; W. A. Meiliche, Janesville; and Henry O. Hagen, New Richland; delegate to the state association, Dr. James F. Lynn, Waseca; and alternate, Dr. Edwin J. Batchelder, New Richmond.——At the annual meeting of the Upper Mississippi Valley Medical Association, held in Little Falls, Dr. Paul E. Kenyon, Wadena, was elected president; Dr. M. A. Desmond, Akely, vice-president; Dr. George H. Lowthian, Akely, secretary; Dr. William Reid, Deerwood, treasurer; Dr. Walter Courtney, Brainerd, censor; Dr. Frank H. Knickerbocker, Staples, delegate to the state association; and Dr. J. Burton Holst, Little Falls, alternate.

MISSOURI

Physicians Ignore Order.—Nine physicians of St. Joseph, who had failed to observe the ordinance requiring them to report cases of communicable diseases, have been cited to appear before the local board of health.

Bequest.—By the will of the late Dr. Ottoway T. Fields, a wealthy colored physician who died March 1, 1910, his medical library, surgical instruments and office appliances are bequeathed to Walden University, Nashville, Tenn., and $1,000 is devised to Provident Hospital, St. Louis.

St. Louis

Section Officers Elect.—At the meeting of the Oto-Laryngological Section of the St. Louis Medical Society, January 25, Dr. Albert F. Koetter was elected chairman; Dr. Max A. Goldstein, vice-chairman; Dr. Eugene T. Senseney, secretary-treasurer, and Dr. Frederick C. Simon, editor.

Social Hygiene Society Meeting.—At a meeting of the St. Louis Society of Sanitary and Moral Prophylaxis, held January 21, the following physicians were elected to office: president, Dr. George Homan; treasurer, Dr. Archer O'Reilly, and members of the executive committee, Drs. Francis L. Bishop, John Green, Jr., Carl J. Luyties, Walter H. Fuchs, Frederick K. Taussig and Bransford Lewis.

NEW YORK

New Society.—The Buffalo Society of Sanitary and Moral Prophylaxis has been organized, and the following officers have been elected: president, Dr. Lucien Howe; vice-president, George A. Lewis; secretary, Ada M. Gates; and treasurer, A. M. Cotton.

Judgment Against Milkmen.—The Supreme Court of Delhi is said to have rendered a judgment of $16,000 against Fishhandler and Abrams of New York for violating the pure milk law by shipping 836 cans of adulterated milk. This is one of the largest judgments ever secured for such a violation.

The Toll of Tuberculosis.—In connection with the tuberculosis exhibit at Ithaca, conducted by the New York State Department of Health and the State Charities' Association, Prof. Walter F. Wilcox, the Cornell statistician, placed the monetary loss to the State of New York from deaths by tuberculosis in 1910 at $64,000,000. He stated that one-ninth of the deaths in the state for last year were due to tuberculosis. Mr. Livingston Farrand, New York City, made a plea for more rural hospitals. Statistics gathered by the State Department for the last four years showed that the death-rate from tuberculosis is decreasing about three times as rapidly in the cities as in the rural districts.

Tuberculosis in Prisons.—Dr. Julius B. Ransom of Clinton prison, Dannemora, N. Y., in an address before the Society of Medical Jurisprudence at the New York Academy of Medicine, on Feb. 13, stated that from 40 to 60 per cent. of all deaths in the prisons of the world are due to tuberculosis and this percentage at times reaches 80 per cent. In this country more than one hundred thousand prisoners are annually discharged to the general community and more than 16 per cent. of these are infected with tuberculosis. Dr. Ransom gave statistics showing that of 46,129 prisoners in the Atlantic and middle west states only 125 are tuberculous, while of 4,624 in five southern states only 125 are tuberculous, and of the 8,540 in the western states only 118. This difference was due to the fact that in the South and West prisoners were put to work in the open air, whereas dust-raising industries in the eastern prisons were conducive to the increase of tuberculosis. Dr. Ransom urged the necessity for a systematic campaign for the treatment of the tuberculous inmates of prisons, jails and detention and charity institutions, advocating special institutions for treatment and the providing of outdoor work.

New York City

Hospitals for Measles.—A seven-story hospital, exclusively for the treatment of measles, with a capacity for 325 patients is to be built this summer at a cost of $275,000.

Bequests.—By the will of the late Mrs. Charlotte Garretson of New Hyde Park, L. I., Presbyterian Hospital is bequeathed $7,500 and the Flushing Hospital $10,000.——The will of Mrs. Caroline Lawrence leaves $20,000 to St. John's Hospital, Yonkers.

Milk Commission Asks Help.—The Medical Society of the County of New York has been appealed to by the Milk Commission to help the certified milk movement by recommending the use of certified milk in their practice. Accompanying the appeal is a description of the conditions under which certified milk is produced.

To Insane Hospital Instead of Penitentiary.—Dr. Ernest H. F. Pirkner, who conducted a so-called sanatorium in West Seventy-Ninth Street, and was recently indicted before the grand jury, tried and found guilty, and was about to have been sentenced to imprisonment in the penitentiary, became violently insane, and has been committed to the Morris Plains Hospital.

Personal.—Dr. Edward G. Janeway has been appointed head of the medical staff of the Presbyterian Hospital, vice Dr. W. Gilman Thompson.——Dr. Simon Flexner of the Rockefeller Institute for Medical Research will deliver the Harben Lectures of the Royal Institute of Public Health of London for 1912.——Dr. Fred J. Leviseur has been appointed consulting dermatologist to the Montefiore Home.

Lectures at Skin and Cancer Hospital.—The governors of the New York Skin and Cancer Hospital announce a course of lectures in the out-patient hall of the hospital every Wednesday afternoon, beginning on March 1 at 4:15 o'clock and continuing until April 26. Dr. L. Duncan Bulkley will deliver the first seven of these lectures and Dr. W. Seaman Bainbridge the last two. The subjects will be eczema, acne, psoriasis, syphilis and cancer.

City Provides Milk Stations.—The Sinking Fund Commission has provided for the distribution of pasteurized milk by the city at cost for the use of infants of poor families. Premises will be rented for the establishment of seven stations in Brooklyn, four in Manhattan and one in the Bronx. The city will employ six medical inspectors, ten nurses and fifteen assistants. The budget contains an item of $40,000 to defray the cost of this work.

The Practice of Midwifery.—At the meeting of the Section on Obstetrics and Gynecology of the New York Academy of Medicine, February 23, Dr. J. Clifton Edgar presented a preamble and resolution, which were unanimously adopted, setting forth that, as 50 per cent. of the births in the large cities of this country are attended by midwives; as the profession of midwifery in the United States is followed by ignorant, untrained and incompetent women; as some of the results of this practice are unnecessary blindness, mental and physical degeneracy and deaths of infants, and unnecessary suffering, invalidism and deaths of mothers; and, as although both physicians and nurses are given instructions in the training and care of childbearing women and new-born infants, provisions are made for the adequate training of midwives, the Section recommends that measures be taken in New York to secure new legislation which shall provide for the training, registration, licensure, supervision, regulation and control of women engaged in the practice of midwifery.

OREGON

Society Meetings.—Physicians of the county met recently at Wallowa Hospital, Wallowa, and organized the Wallowa County Medical Association, and elected the following officers: president, Dr. James H. Thompson, Joseph; vice-president, Dr. Clyde T. Hockett, Enterprise, and secretary-treasurer, Dr. Ralph M. Erwin, Joseph.——At a meeting of the Polk and Yamhill County Medical Association, held in McMinnville, Dr. Asa B. Starbuck was elected president, and Dr. Lenthal A. Bollman, secretary-treasurer, both of Dallas.

Medical College Gets Appropriation.—It is reported that the Oregon legislature has made a special appropriation of $30,000 for the Department of Medicine of the University of Oregon, to be expended for the improvement of the college building, laboratory equipment and current expenses. The regents of the university have made an additional appropriation from the general fund to cover the salaries of two full-time professors. These are Dr. David M. Roberg, who has been secured for the chair of anatomy, and Dr. John McLaren for the chair of physiology.

Personal.—Dr. Fred W. Vincent, Pendleton, who has been confined to the house on account of a fractured rib, is convalescent.——Drs. Eldred B. and Clara Waffle, Portland, started for Europe, January 17.——The office of superintendent of the Eastern Oregon Insane Asylum, which will not be ready to receive patients for a year and a half, and of which the incumbent was Dr. James D. Plamondon, Athena, has been declared vacant.——Dr. Herbert S. Nichols, Portland, has been appointed a member of the Oregon State Medical Board, vice the late Dr. Osmond Royal.——Following a hearing conducted by the Oregon State Board of Medical Examiners, Dr. William T. Eisen, Portland, charged with having procured an unlawful operation which resulted in the death of Mrs. Anna Foleen, the license of Dr. Eisen to practice medicine is said to have been revoked.

PENNSYLVANIA

Personal.—Dr. John B. Chapin, for many years chief of the Insane Department of the Pennsylvania Hospital, Philadelphia, has retired from active duty.

Gift to Tuberculosis League.—Henry Phipps, the first contributor to the Tuberculosis League of Pittsburg, has donated $25,000 to the league on the condition that $150,000 be raised by the members; $118,000 of this amount has already been secured, leaving a balance of only $32,000 to complete the amount.

Election.—At the meeting of the Pottsville Medical Society, February 9, the following officers were elected and installed: president, Dr. George R. S. Corson; vice-presidents, Drs. Merchant C. Householder and Thomas W. Swalm; secretary-treasurer, Dr. John J. Moore, and directors, Drs. George H. Boone, Patrick H. O'Hara and Joseph G. Kramer.

Philadelphia

Morgan Memorial Committee.—The proposed Dr. John Morgan Memorial at the University of Pennsylvania is in charge of Provost Edgar F. Smith, and Drs. S. Weir Mitchell, William Pepper, Jr., Clarence P. Franklin and Swithin Chandler, chairman.

Babies' Club Formed.—For the instruction of mothers in the care of infants and as a further prevention of infant mortality, the Public Health Committee of the Civic Club, has started a "Babies' Club" which meets weekly at the Southwark Neighborhood House. The lectures are really practical demonstrations by the nurse in charge and there is a room fitted up with everything necessary, weighing scales, bath tub and simple remedies.

Meeting Hall Referendum.—As a result of the recent postal referendum on the future place of meeting for the Philadelphia County Medical Society, it has been announced that there were 408 votes in favor of continuing the meetings at the College of Physicians and 197 favoring removal to a more centrally located hall. At the business meeting of the society held on January 18, it was finally settled in favor of the College of Physicians.

Fined in Measles Case.—Accused of having violated the health laws of the state, John L. Worshing, purchasing agent for the Huntingdon and Broad Top Railroad Co., is said to have pleaded guilty, February 2, and to have been fined $20 and costs. The charge against Mr. Worshing was that of removing his son, who was suffering with measles, from the Presbyterian Hospital to his home in Huntingdon before the period of incubation had passed, thereby exposing other passengers to contagion.

Hospital Inquiry Urged.—At the meeting of the Philadelphia County Medical Society on January 18, a resolution was adopted to investigate appropriations to hospitals not under state control. The resolution urges the governor to appoint a joint committee, consisting of three members of the senate, three members of the house, a member of the state board of charities, two licensed physicians, who are not connected with any institution receiving state aid, and a member of the bar, who has served as a manager of a hospital.

Personal.—Dr. George W. Mercher, chief resident physician of the Germantown Hospital is recovering from an operation for appendicitis.——Provost Edgar F. Smith, of the University of Pennsylvania, has been appointed a member of the college and university council in place of C. C. Harrison, resigned.——Dr. Adolph Feldstein, the first resident physician of the Jewish Hospital and for nearly fifty years one of the physicians to the institution, celebrated his seventieth birthday anniversary.——Drs. E. A. McLain and J. E. Murphy have been appointed physicians to the Insane Department of the Philadelphia General Hospital.

Popular Lectures on Tuberculosis.—The popular course of lectures at Logan Hall, University of Pennsylvania campus in charge of a committee of the faculty consisting of Dr. Charles K. Mills, chairman; Dr. Allen J. Smith, dean of the Medical School, and Dr. A. N. Richards, have been most successful. The lecture February 3, was "Tuberculosis from the Sociological Point of View" and one of its main points was that society must remove the ignorant and evil conditions which foster tuberculosis and that the campaign against it is one of education.

Annual Elections.—The following officers were elected for the year 1911 at the recent meeting of the Academy of Medicine: president, Dr. Robert G. LeConte; vice-presidents, Drs. Gwilym G. Davis and John H. Gibbon; treasurer, Dr. Edward B. Hodge; secretary, Dr. Charles F. Mitchell; recorder, Dr.

John H. Jopson, and councilors, Drs. Francis T. Stewart, Thomas R. Neilson and J. Chalmers DaCosta.——The following officers were elected by the Northeast Branch of the County Medical Society: Dr. J. Albert Bolin, chairman; Dr. Albert C. Buckley, clerk, and Dr. Frank Embery, associate vice-president.

SOUTH DAKOTA

Gift to Medical Library.—Dr. Frederick A. Spafford, Flandreau, and Dr. William E. Moore, Tyndall, have each presented to the library of the College of Medicine of the University of South Dakota more than one hundred volumes of medical books, journals and periodicals.

Election.—At the annual meeting of the Eighth District Medical Association, held in Yankton, Dr. Herman J. G. Koos, Scotland, was elected president; Dr. Nelgaard, Volin, vice-president; James Roane, Yankton, secretary-treasurer; and Dr. Silas M. Hohf, Yankton, delegate to the state society.——Watertown District Medical Society, at its annual meeting, elected Dr. Charles S. O'Toole, Vienna, president; Dr. Harry M. Freeburg, Watertown, vice-president; Dr. James B. Vaughn, Castlewood, secretary-treasurer; and Dr. William O. Leach, Carthage, censor.——The Fourth District Medical Society, at its annual meeting in Pierre, elected Dr. Charles M. Hollister, Pierre, president; Dr. Napoleon B. Gerhart, Pierre, vice-president; and Dr. Joseph M. Walsh, Fort Pierre, secretary-treasurer.——At the organization of Gregory County Medical Society, at Dallas, recently, Dr. Harry A. Murnan, Gregory, was elected president; Dr. Edwin B. Bradley, Burke, vice-president; and Dr. Thomas R. Castles, Dallas, secretary-treasurer.

TENNESSEE

Medical College Suspended.—It is reported that the Knoxville Medical College, colored, has been temporarily suspended. There was only one graduate in 1910.

Society Elections.—The Montgomery County Medical Society, at a meeting in Clarksville, February 10, elected the following officers: president, Dr. Frank J. Runyon; vice-president, Dr. George E. Vaughn, both of Clarksville, and secretary, Dr. Lucullus E. Webb, St. Bethlehem.——McNairy County Medical Society, at its annual meeting in Selmer, elected Dr. E. Garry Sanders, Stantonville, president; Dr. James L. Smith, Selmer, vice-president, and Dr. Benjamin C. Dodds, Gravelville, secretary-treasurer.

Improvements at Medical School.—Vanderbilt University has received a donation of $150,000 from the General Education Board as an addition to its general endowment and a like sum from Mr. W. K. Vanderbilt to be used for the medical department. These contributions have made possible the purchase of the campus of the Peabody Normal College which contains 16 acres of ground. On this campus are five or six buildings which are to be used for the medical and dental departments of the university. It is planned also to establish at once a university hospital of at least one hundred beds.

TEXAS

Recommends New Laboratory.—As the result of the inspection of the State Medical College, Galveston, by the subcommittee of the senate, a strong recommendation is made for the construction of a separate chemical laboratory as a necessary addition to the equipment of the institution.

Medical Society Meeting.—DeWitt County Medical Association held its annual meeting in Cuero, February 7, and elected Dr. George W. Allen, Yorktown, president; Dr. William D. Finney, Cuero, vice-president; Dr. Bronislaw J. Nowierski, Yorktown, secretary-treasurer; Dr. Robert Westphal, Yorktown, censor; Dr. W. R. Gillett, Cuero, delegate to the state medical association, and Dr. Harry H. Brown, Yoakum, alternate.

Cities to be Admitted to Census Bureau.—Although Texas as a state is not included in the death registration area of the United States, formed for the compilation and study of mortality statistics by the bureau, there are two cities, Galveston and San Antonio, which because of the effective local death registration ordinances, have been considered in the area of the bureau for the last four years. Owing to the activity of Dr. William M. Brumby, late state health officer, in promoting the extension of the registration area, many requests have been received from Texas cities which desire admission to the area and the chief statistician believes it probable that a number of them, in which the ordinances are thoroughly enforced, will be admitted to the area for the current year.

WISCONSIN

Society Meetings.—At the annual meeting of Brown County Medical Society, held in Depere, Dr. Richard C. Buchanan, Green Bay, was elected president; Dr. Felix Moraux, Luxembourg, vice-president; Dr. Thomas J. Oliver, Green Bay, secretary-treasurer; and Dr. Daniel H. Gregory, Depere, censor.——Langlade County Medical Society, at its annual meeting i Antigo, January 28, elected the following officers: president Dr. Michael J. Donohue (reelected); vice-president, Dr. Georg H. Williamson: secretary-treasurer and delegate to the stat medical society, Dr. John C. Wright, and censor, Dr. Ignatiu D. Steffen, all of Antigo.——At the twenty-fourth annua meeting of the Fox River Valley Medical Association, held i Menominee, Mich., February 7, Dr. Henry W. Abraham Appleton, Wis., was elected president; Drs. Benjamin T. Phillips, Menominee, Mich., and F. Gregory Connell, Oshkosh vice-presidents; and Dr. W. Weber Kelly, Green Bay, Wis. secretary-treasurer (reelected).

Proposed Legislation.—Dr. Cornelius A. Harper, Madison secretary of the State Board of Health and a member of th legislature, has set a good example to other legislators. H has declined to do professional work during the 100 days session of the legislature. He is about to introduce a bil providing for a state sanitary inspector whose duty it will b to travel through the state inspecting hotels, jails, schoo buildings, public buildings of all kinds, streets, alleys an other places to see if they are kept in sanitary condition The bill carries an appropriation of $3.500, one-half fo salary, and one-half for expenses of the office. The secon bill requires counties to make adequate provision for th care of advanced cases of tuberculosis. The state at presen cares for incipient cases, but the State Board of Health wishes counties to take care of their own advanced cases The third reform is the prohibition of the common drinkin cup in all public buildings throughout the state.

GENERAL AND FOREIGN NEWS

Probably Not Plague in Spokane.—The daily press of February 28, reported that Passed Assistant Surgeon Bolivar J Lloyd, U. S. P. H. and M.-H. Service, specially detailed fo this service, has decided that the deaths in Spokane, suppose to have been due to bubonic plague, were not due to tha disease but rather to a complication of influenza and pneumonia.

Cholera in Hawaii.—The Chion quarantine office, Honolul reported on February 25, four fatal cases of cholera amon Hawaiians. Two of these were in the Kewalo suburb of th city, and two at a point nearly a mile distant in the cit proper. On the following day two additional cases wer reported, with one death. All necessary precautions are bein taken by the Board of Health of Honolulu.

Conference on Education and Legislation.—As the Journa goes to press, the seventh annual conference of the America Medical Association on Medical Education and Medical Legislation is holding its opening session. The program was give in The Journal recently. An account will appear in thes columns later and the full report will be published in th *Bulletin of the American Medical Association.*

Meeting of the Association of Colleges.—At the meeting o the Association of American Medical Colleges in Chicag February 27 and 28, a number of amendments to the constitution were adopted, the principal one being in regard t the new curriculum for medical colleges and the raising of th entrance requirements to an unconditioned high-school certificate. Another amendment was the placing of the administration of the entrance requirements into the hands of prope educational authorities. The following officers were elected president, Dr. William P. Harlow, University of Colorad Boulder; vice-presidents, Drs. Henry A. Christian, Harvar Medical School, Boston, and Charles M. Hazen, Medical College of Virginia, Richmond; secretary-treasurer, Dr. Fred C Zapffe, Chicago (reelected), and judiciary council, Drs. William J. Means, Columbus, O.; Randolph Winslow, Baltimore Clarence M. Jackson, Columbia, Mo.; Charles R. Bardeen Madison, Wis.; Egbert LeFevre, New York City; James F Guthrie, Dubuque, Ia., and John A. Witherspoon, Nashvill Tenn. The next annual meeting will be held in Chicago.

Bureau for Distributing Bacterial Cultures.—The Departmen of Public Health at the American Museum of Natural Histor has equipped a laboratory to serve as a central bureau for th preservation and distribution of bacterial cultures of bot pathologic and non-pathologic organisms. It is hoped that th laboratories of medical schools, colleges, boards of health, agriculture experiment stations, and individuals engaged in bio chemic work will furnish the museum with cultures in their possession. Types of new species and varieties are particularly desired at present. The laboratory plans also to keep on file descriptions of bacterial species in print or arranged in the form of standard card, and will be grateful for copies of any such descriptions. Descriptions filed in the department will be carefully preserved and living cultures will be supplied at all times without charge to corresponding laboratories, and so far as possible, and with a reasonable charge, to schools and other institutions which may desire cultures. Pathogenic forms will be sent only to properly qualified persons. The headquarters of the department are at Seventy-Seventh Street and Central Park West, New York City.

Sanitary Association Meeting.—At the fourth annual meeting of the Lake Michigan Sanitary Association, held in Chicago, February 18, addresses were made by R. R. McCormick, formerly president of the sanitary district, in which he stated that the power to protect the waterways from pollution rests with the federal government; and that if the people of the states of Wisconsin, Illinois, Indiana and Michigan do not take proper action the government will forbid all communities to empty refuse into Lake Michigan or adjacent waterways. Surgeon George B. Young of the U. S. Public Health and Marine-Hospital Service, discussed legislation now pending in congress relative to sanitation; Dr. Mazyck P. Ravenel, of the University of Wisconsin, spoke on "The Water of Racine, Kenosha, and Milwaukee;" Frank A. Windes discussed the progress in the improvement of north shore sanitary conditions; Langdon Pearse, of the sanitary district, spoke on "Sewage Disposal"; J. Herbert Brewster, of the Indiana State Board of Health, made a report on the condition of the Calumet River from Gary to its mouth; and Health Commissioner, Dr. William A. Evans, Chicago, discussed sanitary conditions.

Good Sanitary Conditions in Havana.—The *Revista de Med. y Cirugia* of Havana publishes an open letter from Dr. J. Guiteras, chief of the public health service of the island, protesting against certain statements that appeared in the *Boston Transcript* and were copied in the *Army and Navy Journal*, Oct. 10, 1910, to the effect that Cuba was dropping back into her old apathy in respect to sanitary matters. He deplores the fact that every year at the opening of the tourist season some paper in the United States makes some such statement and that it is copied from one to the other until it seems important enough to be reproduced by some standard periodical which does not take the trouble to verify its accuracy. On the contrary, Guiteras states in 1909 there were only forty-five deaths from typhoid at Havana, with a population of 300,000, and thirty-eight in the first eleven months of 1910; there has been no mortality from yellow fever for years; from tuberculosis it has been only 13.07 per 10,000 inhabitants, and the infant mortality has constantly declined, dropping from 196 in 1900 to 171 for each 1,000 births, while in the entire island it is only 116. The deaths from malaria have dropped from 19 in 1908 to 6 in 1909, and the general mortality of the island now is only 13 per 1,000. The republic goes to great expense throughout the island to keep up the mosquito campaign, but in 3,056,118 houses examined only 6,238 actual breeding-places were discovered.

Proposed Organization of the Profession in Cuba.—The Cuban Academia de Ciencias Medicas, Fisicas y Naturales, located at Havana, recently sent out an appeal signed by its president, Professor J. Santos Fernandez, to all the medical men of the island inviting them to a national gathering to discuss ways and means for organizing the profession to protect its material and other interests. At the meeting resolutions were adopted to have a petition drawn up to be presented to the national legislature asking for compulsory organization of the registered physicians of the country, regulation of the illegal practice of medicine, establishment of a minimum salary for medical state officials, with an increase of 10 per cent. for each five years of service, correction of hospital abuse by those able to pay, contract practice restricted to 500 policy-holders to one medical officer, etc. In the discussion of the subject one speaker cited the universal dissatisfaction with conditions in regard to contract practice in France, England, Germany and Spain, where the medical men have finally had to organize to protect themselves against further exploitation by outside interests. In Belgium, he added, the physicians have triumphed over these evil conditions, thanks to the union of their common interests in concerted action. The idea of organization in Cuba being made compulsory is combated by other physicians, the opposition being so wide-spread that it will probably cause the whole matter of organization of the profession in Cuba to be tabled for the present, although the leaven of the need for organization is surely working.

MANILA LETTER

(From Our Regular Correspondent)

MANILA, Jan. 14, 1911.

Health and Sanitation in Indo-China

During a Christmas vacation just ended, I made a trip to Indo-China and while there visited some of the hospitals and inquired into the general health of the country and the sanitary measures in vogue. Indo-China is a French possession and the stronghold of the French in the far East. It is located south of the Canton district of the Chinese Empire and east of Siam and the Malay peninsula. The country has been under the control of France for about sixty years. During this time many improvements have been made and the country has many of the landmarks of western civilization. The roads are excellent and most of even the smaller towns are supplied with the best available water and possess underground sewage systems. Many of the latter improvements, however, are doubtless for the convenience and health of the government functionaries, most of whom are French. One quickly gathers the impression that the native gets far less consideration in Indo-China than in the Philippines. House servants get from $4 to $8 (Mex.) (about $1.80 to $3.60 U. S. standard) per month and the great mass of the rice-field laborers who make up by far the majority of the population are still permitted to live in the dingy little nipa shacks which usually are found in groups in a filthy swamp. In many respects Indo-China resembles the Philippines, both in climate and in topography.

The principal diseases of the former are said to be dysentery, skin diseases and malaria. Dysentery is quite prevalent and is often very severe on the European. It is asserted that bacillary dysentery is not found in the country, but the quickness with which people sometimes die with dysentery there would tend to make one a little skeptical. Cases often terminate fatally in one to four days. A source of a great deal of the dysentery, especially among the Europeans, is from fresh vegetables, both those from the local market and those imported from China. In either case they are grown by Chinese, and the Chinaman's system of gardening is not a particularly sanitary one. Human and animal excreta are collected in a cesspool or well and the whole mass of excreta and water is churned up into a fine emulsion. Each evening the truck garden is sprinkled from this pool. Thus fertilization and irrigation are accomplished at the same time and the vegetables thrive. This kind of vegetable naturally has a tendency to produce more fertilizer and the "heathen Chinee" profits additionally. As might be expected when vegetables of this kind are not well sterilized, there results serious infection with various microorganisms. This is probably the source of most of the dysentery among Europeans in Indo-China.

In the tropics, green vegetables, lettuce, tomatoes, etc., are especially palatable and one is tempted to eat them even when one has no assurance that they have been properly prepared.

Liver abscesses are quite common among the soldiers of Indo-China. At the hospital in Saigon there are several cases (four to ten) for operation each week. The Public Health Reports show a few cases of bubonic plague and cholera each week, but they seldom become epidemic. Yaws is said to be practically unknown in Indo-China, and leprosy occurs less frequently there than in the Philippine Islands. In regard to the occurrence of yellow fever, I was told that it was believed not to exist or at least is of very rare occurrence in recent years, but that when the French were attempting to dig the Panama Canal, it was always a source of anxiety and that cases appeared from time to time.

Major E. R. Whitmore, who has made a more extended tour of French Indo-China and a more complete inquiry into the medical problems of that country, has reported his observations to the Manila Medical Society for comparison with those of the Philippines. Among his notes are the following:

"The director of health is an army medical officer as well as the subdirectors. The army medical officers also furnish the quarantine service, such as boarding ships, etc., and do most of the teaching in the Medical School of French Indo-China at Hanoi. The manufacture of opium is a government monopoly and apparently there is no great restriction on the sale of the drug.

"The military hospitals are large permanent structures of brick, concrete and steel. In connection with the military hospitals at Hanoi is the Antirabic and Bacteriologic Institute of Hanoi. Drs. Mathis and Leger (majors of the colonial service) have done a great deal of work and have published freely on the diseases in Tonkin due to animal parasites. They have worked on the diseases around Hanoi and have charted the various diseases in that part of Tonkin down to Haiphong and for some distance north and south on the coast.

"They have found that infection with *Filaria nocturna* is very frequent among the natives in north Indo-China and especially in Hanoi and Haiphong.

"Relapsing fever has been epidemic in Tonkin during the years 1907, 1908, 1909. It is especially prevalent in the delta of the Red River around Haiphong.

"Malaria is prevalent in Tonkin and the endemic index has been worked out to some extent. The endemic index (2 per cent. of apparently healthy children from 1 month to 5 years old found infected) runs according to the locality from 2.98 to 40.00 with an average of 7.33. It is interesting to note that their findings show that a large per cent. of the infections in children under 1 year are tertians, while quartans and subtertians are not nearly so numerous. But as the age of the child increases the proportions of quartan and subtertian infections increase as the tertians fall. However, they point out that their figures are still too small to base any conclusions on them.

"In connection with their work on malaria they have worked on the mosquitoes in Tonkin; six species of anophelines have been found in Tonkin, three in Hanoi.

"Infection with the Chinese liver-fluke is very common among the natives in north Indo-China and increases with age. Varying with the place, from a quarter to a half of the natives are infected with this fluke.

"They have studied the intestinal parasites of man in Tonkin and find infection about as common and with the same parasites as in the Philippines. Of a thousand natives examined, every one had at least one intestinal parasite, and the 1,000 had 2,289 infections.

"Intestinal amebiasis is very prevalent among the Europeans in French Indo-China. In the wards of the Military Hospital in Saigon they average about forty cases of it, and about eighty cases pass through the hospital every month.

"I saw three cases of sprue in Saigon and was informed that it was not very uncommon there, while the doctors in Hanoi told me that they do not have any sprue in Hanoi.

"Rabies is wide-spread among the animals, especially dogs, and the two institutes in Saigon and Hanoi have constantly from seven to thirty persons undergoing protective inoculations. Beside the rabies work, the Pasteur Institute at Saigon prepares vaccine virus and undertakes the study of material from infectious diseases, as plague, cholera, typhoid; of which diseases there are usually a few cases.

"At Nha Trang the anti-rinderpest serum is prepared, but all other serums (antidiphtheritic, etc.) are sent out from Paris.

"I was especially struck by the difference in the animal parasites found in the natives in Indo-China and what has been found in the Philippines. This is all the more striking when we remember that in Tonkin (in about the same latitude as Luzon), relapsing fever is epidemic, and infection with the liver-fluke is very prevalent. Relapsing fever has not been found in the Philippines, except an occasional imported case, and the liver-fluke is found only in Chinese who have probably brought it in with them.

"Similar conditions seem to hold good for parasites of lower animals, though this has not been worked on as much here as there, and save for the trypanosomes of rats and bats (which seem to be infected everywhere) little is known of the parasites of the lower animals in the Philippines.

"A hematozoon is found rather commonly in monkeys there, while D. Teague has examined a large number of monkeys here without finding a hematozoon and I think no one has ever found a hematozoon in monkeys here.

"I have examined the blood of doves, snipe and ducks without finding a leukocytozoon, while doves are commonly infected with a leukocytozoon there.

"But possibly when more work has been done on the animal parasites of man and the lower animals in the Philippines, we shall find that French Indo-China has not so many more animal parasites than we have."

LONDON LETTER

(From Our Regular Correspondent)

London, Feb. 14, 1911.

The Lowest Birth-Rate and Death-Rate on Record

The continuous fall of the birth-rate in recent years is once more shown by the lowest birth-rate on record. The figures for 1910 have just been issued; the births numbered 897,100 and the deaths 483,321, the natural increase of population thus being 413,779. The average annual increase in the past five years was 404,656. The birth-rate was at the rate 24.8 per 1,000 of the population, which is 0.8 below the rate of 1909, and lower than any rate on record. Compared with the average of the decade 1900-1909 the birth-rate in 1910 showed a decrease of 2.7. The death-rate in 1910 was 13.4 per 1,000, which was 1.1 below the rate of 1909 and, again, the lowest record. Compared with the average of the decade 1900-1909, the rate in 1910 showed a decrease of 2.4. The deaths included 10,609 from diarrhea, 8,574 from whooping-cough, 8,172 from measles, 4,177 from diphtheria, 2,337 from scarlet fever, 1,848 from typhoid, and 19 from small-pox. Thus 35,736 deaths were due to these epidemic diseases, a rate of 0.99 per 1,000, against 1.28, 1.34 and 1.13 in the three previous years. The deaths of infants under one year of age was 106 per 1,000 births, which is three below the rate of 1909 and the lowest on record.

The Value of Heredity

At the Authors' Club Dr. G. Archdall Reid, the author of "The Principles and Laws of Heredity," opened a discussion on this subject. He said in part: Everyone believes in evolution, which implies adaptation to the environment; degeneration implies the contrary. All plants and animals are adaptional forms. Man and the beetle can live in their own environment but not in that of each other. The right theory of evolution, and the right theory of heredity must fit in with this fact of adaptation. Only one theory of heredity fits the facts—Darwin's theory of natural selection. Selection implies a selective mortality, that the fittest survive and the unfittest perish as a general rule. Many people die young because they are weak against various microbic diseases. Each disease weeds out in its own habitat the unfittest. One other source of elimination is alcohol to which people vary in susceptibility. If the ill conditions which affect the parent do not as a general rule tend to alter offspring then since the offspring does vary spontaneously the fit will be preserved and the unfit will be weeded out and the race undergo protective evolution. A very unhealthy condition is found in the slums of great cities which show unhealthy parents and puny children. Since the fit will survive the race will become more resistant to slums. The races most exposed to slum life are Jews and Chinese. These races have not grown degenerate but have undergone protective evolution. The races longest exposed to consumption are most resistant to it. Offspring is not rendered degenerate by the misfortune of the parents but races undergo evolution owing to the fire to which they have been exposed. Suffering does not affect a race; but the deaths of the race do. By means of these deaths the foundations of the empire are laid. Disease has created a void which the British have filled in Australia and New Zealand.

Typhoid and Water Storage

Dr. A. C. Houston, bacteriologist to the Metropolitan Water Board, has issued an important report on the vitality of typhoid bacilli in stored water, and with that of cultivated as opposed to uncultivated bacilli. Bacilli derived from a typhoid carrier and bacilli cultivated in the laboratory are added in similar proportions to samples of river water in a carefully conducted and protected series of experiments. Both varieties proved to be incapable of sustaining an independent existence during storage and perished within definite limitations of time, Dr. Houston concludes that even a week's storage of raw river water is an enormous protection and less than a month's storage an absolute protection against typhoid, and that it is in the power of the board by adequate storage to render the supplies drawn from rivers, however originally polluted, perfectly safe before filtration.

The Overcrowded Medical Curriculum

The progress of medical science renders increasingly difficult the teaching of the medical student all the subjects which it is tuought he should master before he is allowed to practice. Some years ago, the time for the completion of medical studies was increased from four to five years, but the longer period has still proved too short and only a minority of students complete their curriculum in that period, six and one-half or seven years being usually required. The subject has engaged the attention of the General Medical Council (the body appointed by the government to supervise medical education and exercise discipline over the profession) but no solution of the difficulty has yet been found. A committee was appointed to consider the place in the student's career which the preliminary sciences should occupy and to frame and submit to the council a pattern scheme of medical education, whereby the required minimum of the several subjects to be included in the curriculum could be adequately studied, and the requisite examinations thereon be passed within the period prescribed by the curriculum. The committee has declared itself unable to suggest any remedy for the congestion of the medical curriculum. To meet the difficulty, Sir Henry Morris, a member of the council, proposes that the preliminary scientific studies, such as chemistry, physics, botany and zoology, which now form part of the curriculum, should be removed from it and pursued by the students in the schools, leaving the five years of the curriculum free for the strictly professional subjects, anatomy, physiology, medicine, etc. The council, on the other hand, holds that as the supreme authority in medical education it cannot sanction any part of the medical education being undertaken except under its control. This objection seems captious and unreasonable. The greater part of the education of the student before he enters medicine is necessarily outside the control of the council and adding to it chemistry, physics, etc., involves no question of principle. By means of a preliminary examination the council could easily insist on an adequate knowledge of these subjects before the beginning of the medical curriculum.

Infectious Diseases in London in 1910

The returns just published of the Metropolitan Asylums Board (which controls all the fever hospitals of London) shows several facts of interest. During 1910, 15.053 patients with the most important of the infectious diseases were admitted to the hospitals. These diseases were as follows; scarlet fever, 9,682 cases; diphtheria, 4,698; typhoid fever, 673. Two hundred and six deaths from scarlet fever occurred, being a case-mortality of 2 per cent. This number is less than half the average annual number of the preceding nine years, and lower than that in any year for which statistics exist. There were 360 deaths from diphtheria in the hospitals, a case-mortality of 8 per cent. The total deaths from diphtheria in London during the year were 434. In the three preceding years the deaths numbered 781, 724 and 605 respectively, showing a steady decline which reached its maximum last year. The deaths from typhoid fever in the hospitals numbered 126, a mortality of 19.5 per cent. The total number of deaths in London was 198,107, below the average in the nine preceding years, but an increase of fifty-two on the unprecedently low number of 1909. Thus the mortality of scarlet fever in the metropolis has shown in recent years a continuous decline, the disease being evidently of a milder type. On the other hand the case-mortality of diphtheria and typhoid shows no such decline.

PARIS LETTER

(*From Our Regular Correspondent*)

Paris, Feb. 10, 1911.

Radiography as a Means of Ascertaining Whether or not an Infant has Lived

The means of medicolegal investigation to ascertain if a child has lived or not have hitherto been much restricted and have offered no absolute certainty. It appears from the researches which Dr. C. Vaillant has reported to the Académie des sciences that radiography offers a means of determining this point. If the fetus has not lived, no organ is visible, even if radiography is practiced after the eighth day in summer and the fifteenth day in winter. Later on, in frozen subjects, the whole arterial and venous system becomes visible on the negative, because putrefaction begins in the organs which functionate during intra-uterine life. On the other hand, in the bodies of infants which have lived, all the organs are visible if radiography is used as late as the tenth day after death. The only perceptible modification is produced by the augmentation of gas in the abdominal organs. There is no room for error in the interpretation of the results of radiography, whether it is used immediately after birth or later, since in either case the results are different in the case of an infant which has lived from those in a fetus which has not lived.

Relapses and Complications After Injections of Salvarsan

On February 2, before the Société française de dermatologie et de syphiligraphie, Dr. Bodin reported the case of a patient with precocious malignant syphilids which were intractable to treatment with mercury and iodids, but which were cured within fifteen days after an injection of 55 cg. of salvarsan. A month afterward, however, the patient had a relapse which yielded to a new injection of salvarsan, relapsing a second time at the end of forty-six days.

Moreover, Professor Gaucher and Dr. Gougerot observed complications following immediately after injections of salvarsan (two cases of pulmonary embolism with sharp pain, and respiratory difficulty a few minutes after the injection, continuing for several hours), and later complications (two cases of phlegmasia alba dolens) appearing four or five days after the injection.

The Reform of Medical Instruction

The Association corporative des étudiants en médecine has just decided to demand: (1) the limitation of *stagiaires* to the number of twelve for each hospital service, which necessitates the extension of the *stage* to a greater number of services; (2) the creation of a superior medical council, composed in part of the professors of the Faculté, and in part of the delegates of the medical *syndicats*, with consultative voice for the corporative associations of medical students.

Moreover, considering that the organization of professional instruction demands a more complete reform of the hospital *stage*, the association demands an investigation looking toward the modification of the externship by which it should become a function open to all students by an examination and not by a *concours* as is the case at present. The association believes that all medical students should exercise this function for at least two years to obtain the diploma of doctor of medicine.

The Laborie Prize

The Société de chirurgie has divided the Laborie prize for 1910 as follows: $400 (2,000 francs) to Dr. Paul Sourdat of Paris for his radiographic study of tuberculosis of the bones and articulations, coxalgia and white swelling of the knee; $160 (800 francs) to Drs. Jules and André Boeckel of Strasburg for their study of the fractures of the spine without medullary symptoms; $100 (500 francs) to Dr. Guibé of Paris for his paper on the paralysis of the suprascapular nerve.

Personal

Dr. A. Kelsch, former *médecin inspecteur* of the service of military hygiene and member of the Académie de médecine has just died. After holding professorships in various French medical schools, he was appointed to the military hospital of Algeria, but was recalled to Paris two years later as professor of epidemiology at the Ecole d'application du service de santé militaire du Val-de-Grâce. In Algeria he accumulated much material on paludism, dysentery, liver abscesses, etc., which he utilized in the treatise on the diseases of warm countries, by himself and Kiener. He was the author also of a treatise on epidemic diseases in several volumes and numerous papers on epidemiology and hygiene presented before the Académie de médecine.

Dr. Claude Martin of Lyons, who had acquired great reputation in the practice of prosthesis of the face and mouth, has recently died. He was connected with the Hôtel-Dieu de Lyon, and was one of the most valued collaborators of Professor Ollier in all the procedures on the face which required the use of prosthesis appliances. He was appointed in 1908, national correspondent of the Académie de médecine de Paris.

Dr. William J. Mayo, of Rochester, Minn., is one of the foreign correspondents recently elected by the Société de chirurgie de Paris.

BERLIN LETTER

(*From Our Regular Correspondent*)

Berlin, Feb. 10, 1911.

Personal

The noted Berlin physiologist, Prof. H. Munk, has been given the honorary title of doctor by the veterinary school.

R. Stern, director of the medical policlinic and head physician of All Saints Hospital at Breslau, died Feb. 1, of influenza, aged 45. In 1892 he joined the faculty as privat-docent. His work lay mostly in the field of experimental pathology, but he was chiefly known by his treatise on "The Traumatic Origin of Internal Diseases," which for the first time systematically set forth the importance of trauma in internal pathology. The book had a wide circulation. A few years ago some interest was aroused by the fact that Stern accepted a call as director of the internal medicine clinic at Greifswald and later declined it without special reason. At one time there was a rumor of mental aberration. He traveled for some months, but later resumed his work at Breslau, and at the last meeting of the scientific association at Königsberg he delivered a fine address on a bacteriologic theme.

The Journey of the Crown Prince Interrupted by the Plague

In consequence of the extremely severe outbreak of the plague in eastern Asia, the German Crown Prince has abandoned his tour of the world and will begin the return journey at Calcutta. As the wide extent of the plague in northern China precludes the return by the trans-Siberian railway, he will come back by way of the Red Sea. Terrible reports are made in the newspapers regarding the daily spread of the disease in China. Probably the reports are exaggerated, and it is to be assumed that the epidemic had begun before the Chinese authorities permitted reports of it. According to statements made in the Reichstag by a representative of the imperial naval office, Tsingtau, a city lying in the German protected area, is threatened by the plague. As a result the city is isolated on the land side by a military cordon, the railroad is interrupted at Syfang, all persons remaining in the city are kept under strict surveillance, and all ships are subjected to quarantine. The military surgeons who have recently been discharged and were about to return to Germany will remain in Tsingtau. The Chinese government has requested the German government to send European physicians to the region infected with plague. Russia has suggested an international commission to investigate the conditions of the epidemic on the spot. As a precautionary measure our imperial health council will take up the question how far Germany itself is threatened by the plague, and formulate measures of protection at the proper time.

The Campaign Against Lupus

The department of education recently notified all school principals of the danger of lupus and the necessity for its early recognition and proper treatment. It also warned the medical inspectors of schools to pay especial attention to lupus cases and report to the school director any found.

Instruction of Soldiers on Tuberculosis

In a suburb of Berlin, Wilmersdorf, a tuberculosis exhibition was installed a few weeks ago by the municipal authorities to educate the public. Statistics on the spread of tuberculosis, anatomical preparations and directions for the repression and prevention of tuberculosis, are shown, and lectures on these subjects are held together with other matters of the same sort. Lately more than 100 under-officers of the Berlin garrison have been conducted through the exposition daily by military surgeons and instructed with reference to the significance of the individual objects on exhibition.

Presidency of the Berlin Medical Society

At a session held for the purpose a few days ago, Senator declined a reelection as first president on account of his advanced age. As Senator has lately been failing in energy the society accepted his resignation and selected Professor Orth, the director of the pathological institute, in his place. Professor Kraus, director of the second medical clinic, was elected as one of the three vice-presidents in the place of Orth.

International Prize Competition of the Red Cross

In 1902 the Empress Maria Feodorowna, protectress of the Russian Red Cross, established the "Empress Maria-Feodorowna Foundation," a fund for the purpose of promoting new inventions which are intended to relieve the suffering of the wounded and sick on fields of battle. The income from the capital is to be distributed every five years on the occasion of the International Red Cross Conference. This was done first at the seventh conference in London, 1907. For Germany at that time the Doecker's barrack system and the Linxweiler system of transportation were each rewarded with a premium of $1,500 (3,000 rubles). The next competition occurs at the international conference in Washington, 1912. The income accumulated for distribution amounts now to about $10,000 (40,000 marks). The German member of the jury of awards is Professor Pannwitz of Charlottenburg.

International Scientific Research Trip to the Canary Islands

A scientific study trip to Teneriffe will occur in March and April of this year. In the spring of 1910, at the suggestion of Professor Pannwitz, president of the international commission for investigation of altitude and sunlight, a scientific expedition to the mountainous region of Teneriffe was undertaken, in which under the direction of Professor Zuntz, German, Austrian and English physiologists as well as the astronomer Mascart, of Paris, and Professor Müller of Potsdam, took part. Further investigations on the action of light in those especially illuminated regions are to be undertaken, for which German, Russian and Danish investigators have promised their cooperation.

Complete Edition of the Works of Robert Koch

At the request of the heirs of Robert Koch, that is, his second wife and the daughter of his first wife, a complete edition of the works of this gifted bacteriologist will be published by Professor Schwalbe with the cooperation of Professor Gaffky, director of the institute for infectious diseases, and Professor Pfuhl, Koch's son-in-law. In particular, the different articles scattered in various journals and now difficult of access are to be collected. In addition to the articles already published, suitable material selected from the numerous reports that Robert Koch made for the government authorities will be published for the first time. It is expected that the work, which is appearing under the care of the well-known publisher, Georg Thieme of Leipsic, will be completed by the end of the year.

Increase in Fees for Foreign Students at the Prussian Universities

For some years the demand has been made in the Prussian parliament (Landtag), as I have previously informed you, to raise the matriculation and tuition fees for foreigners in the universities and technical high schools. The authorities have hitherto been opposed to this, principally because they feared that similar restrictions would be imposed against German students in the foreign universities. Now, inasmuch as the home students are being crowded out sometimes by foreigners, the authorities have yielded so far that they have imposed for the summer semester of 1911 a double fee on foreigners for laboratory work and attendance on lectures. For students of the natural sciences and medicine this amounts to an increase of $2.50 (10 marks) and for other departments $1.25 (5 marks).

The Death-Rate in Relation to the Standard of Civilization

Dr. Prinzing, the medical statistician of Ulm, published in the last number of the *Archiv für Rassen- und Gesellschaftsbiologie* a very interesting study of the development of civilization from the standpoint of the death-rate. He states that the high infant mortality in countries with a low state of civilization is probably chiefly attributable to the great prevalence of acute infections. Among adults the mortality of males in the more highly civilized countries approaches that in the less civilized because of the unfavorable influences of industry and of the abuse of alcohol, while the mortality of the female sex is greater among the less civilized because of their lack of protection and the excessive demands made on their productiveness. In civilized countries old age is characterized by a higher mortality because in these countries the working power of old men very frequently cannot be sufficiently utilized. It might be assumed that the slight difference in the death-rate in the adult period depends on the fact that by the high mortality of children in the less civilized countries, the weaklings are eliminated and only the most resistant remain. But the death-rate of the first year of life must be viewed apart because, for example, in spite of their slight infant mortality, Servia and Bulgaria show the same death-rate as Hungary and Russia, with their high infant death-rate. Also the numerous deaths in later childhood in these countries can have only a small influence on the question as very many of them are caused by infectious diseases and their results, in which cases the mortality depends less on hereditary resistance than on the occurrence and virulence of the infection.

We cannot assume that those predisposed to tuberculosis are early eliminated by the great infant mortality in eastern Europe and that by this means the mortality of adults is diminished; for the mortality from tuberculosis is greater in these countries than in western Europe. Furthermore we have seen that the slight difference in mortality of adult males in eastern and western Europe depends not on an especially low mortality in the east, but on an increase in the mortality in the civilized countries by the factors above named. Still it would be incorrect to deny that the high infant mortality of eastern Europe has any influence on the less unfavorable mortality of adults. In a number of infectious diseases (e. g., small-pox, measles, scarlet fever, typhoid fever) immunity is induced by a single experience of the disease, so that many persons are protected in later life by having had these diseases in childhood, although on the other hand, these children's diseases cause many deaths. If the children in these countries could be protected by any measures against infections, they would in later life fall victims to these diseases in increased measure, under the ordinary conditions of adult life. Here we have to do with an acquired peculiarity. Opinions differ as to whether there is a congenital hereditary immunity; at any rate, it is very rare in case of diseases like small-pox and typhoid fever. In respect to certain diseases the adult civilized man does not need to acquire an immunity, which is secured only with such great sacrifice of human life, for he knows how to protect himself in a simpler way, by vaccination against small-pox, by general hygienic measures against typhoid fever and similar diseases, and by early isolation of patients or by avoiding them himself in case of other diseases. If a Servian or Russian family wishes to have three children who shall reach at least the age of 14, there must be five or six born in this family, whereas in an English family only four births would be necessary for the same purpose. This is without doubt of great value for the latter nation, as every birth means danger to the life of the mother, necessitates temporary inability to work and the trouble and expense attending the rearing and death of young children. It is not very probable that by the selection of four instead of five or six children, the likelihood of preserving lives of inferior value is markedly increased, for in civilized countries, in the majority of the population, that is, the working classes, the preservation of doubtful lives is rare. In this respect from an economic point of view there can be no doubt that the death-rate which is common in the more highly civilized countries, consisting of a low mortality before the age of 35, constitutes a great gain for these nations.

VIENNA LETTER

(From Our Regular Correspondent)

VIENNA, Feb. 14, 1911.

An Excursion of the American Medical Association of Vienna

The American Medical Association of Vienna has been mentioned several times in previous letters in THE JOURNAL. It has at present a fully recognized position among the medical associations of this city, and is held in high esteem by its Austrian confrères. Recently, the association was invited to visit the Leuwering, a favorite health resort, about 80 miles south of Vienna, where splendid accommodations for health-seeking patients were erected a short time ago. The American physicians—a party of about eighty—were led through the two hydrotherapeutic establishments situated some 3,000 feet above sea level, and were shown the various electric and other physical equipments there. The local magistrates and the medical men of the district were unanimous in declaring that the visit of the foreign physicians was regarded as very flattering, while on the other hand, the invitation shows what a position the American association has attained here, for this kind of excursion is not very frequent in this country.

A Students' Strike in Cracow

The appointment of a reactionary professor of philosophy named Zimmermann in the University of Cracow has led to serious consequences in hospitals of that city. The majority of the students there belong to the liberal or anticlerical party. They remonstrated against the professor, and as the appointment was not cancelled, riots and other disturbances followed. Medical students took the lead in these demonstrations. It seems to be the privilege of medical students, at least in this country, to be always at the head in the defense of the liberty of teaching. A number of students were suspended for at least one term, while others were excluded permanently. These severe measures produced a general strike at the university, and since numerous medical students of the higher classes or near graduation were busy in the hospitals, they too had to strike. This serious condition has been prevailing for some time, and the senate of the university has been forced to reconsider its decision; the lack of students is felt keenly in the wards and the radical mind of medical thinkers seems to be predominant in students' circles. They will not give in before the "disease," the reactionary experiment, has been eradicated.

Titles for Practitioners

It is intended to grant certain titles to distinguish medical men not holding hospital or similar appointments in this country. The titles are to be "Medicinalrath" and "Ober-Medicinalrath," which mean in fact nothing but sound imposing. In several medical corporations an energetic movement has been set on foot to prevent the passing of such a bill by the board of health, within whose jurisdiction this matter falls. The possession of such a title would, in the opinion of those who oppose the idea, give an unfair advantage to these men, for our public is very fond of titles and believes that a title is equivalent to better knowledge. Hence the title of "privat-docent" for instance, is much coveted by physicians here. We have already many titled doctors. In Vienna alone, over 20 per cent. of the total have the title of "Professor," "Docent" or "Assistant," and in the country titles mean even more, being less common. It is therefore likely that the opposition will carry the day.

Death of Professor von Braun

The Nestor of the gynecologists of this city, Professor von Braun, died after a short illness a few days ago. He was the last one of the old Vienna medical school, which counted Skoda, Rokitansky, Billroth, Kaposi and Nothnagel among its members. Professor Braun was the first teacher of midwives in this country, and his earnestness, dexterity and sagacity soon gained for him a leading position and an enormous private practice in the highest circles. He found time for useful scientific work and published writings on extra-uterine pregnancy; the fetal malformations; the anatomy of the pelvis, and obstetric surgery. His death at the ripe age of 82 came as a shock to his numerous friends.

Marriages

REUBEN FRANK DAVIS, M.D., to Miss Bessie Lee Leckey, both of Glasgow, Va., February 15.

GEORGIANA MARGARET DVORAK, M.D., and John Joseph Theobald, both of Chicago, Oct. 29, 1910.

HARVEY WASHINGTON WILEY, M.D., Washington, D. C., to Miss Anna Campbell Kelton, February 27.

FREDERICK WILLIAM MAYER, M.D., Indianapolis, to Miss Margaret Welch, at Indianapolis, February 8.

DAVID WAYNE FOSLER, M.D., Indianapolis, to Miss Katherine Krauss Vonnegut, at Indianapolis, February 28.

ALBERT JULIUS GEIGER, M.D., U. S. Navy, to Miss Margaretta Benners Ashbridge of Philadelphia, February 15.

JOHN WATKINS WILLIAMS, M.D., Everetts, N. C., to Miss Bertie Zenobia Gardner of Williamston, N. C., January 18.

JONATHAN D. HINSHAW, M.D., Canon City, Colo., to Miss Elizabeth Love of Silver Cliff, Colo., at Canon City, February 8.

ORVILLE E. SPURGEON, M.D., Muncie, Ind., to Miss Ella Maria Worley of Washington Court House, O., at Muncie, January 18.

Deaths

Aloysius Oliver Joseph Kelly, pathologist, and diagnostician, editor of the *American Journal of the Medical Sciences*, died at his home in Philadelphia, February 23, from complications following an attack of influenza, aged 41. He was a native of Philadelphia, received the baccalaureate degree in arts in 1888, and three years later the degree of M. A. in LaSalle College. He graduated from the Medical Department of the University of Pennsylvania, Philadelphia, in 1891, and for two years did postgraduate work in London, Dublin and Vienna, where he devoted special attention to pathology and internal medicine. He was associate professor of medicine in his alma mater; professor of the theory and practice of medicine in the University of Vermont, College of Medicine; and professor of pathology in the Woman's Medical College of Pennsylvania, Philadelphia. He was a member of the American Medical Association, Association of American Physicians, and American Association of Pathologists and Bacteriologists; a fellow of the College of Physicians of Philadelphia, and of the American Academy of Medicine. He was visiting physician to St. Agnes and University Hospitals, and pathologist to the German Hospital. His literary work included a text-book on the practice of medicine, published in 1910; the joint editorship, with Dr. John H. Musser, of an extensive system of therapeutics; and, as stated above, he was for several years editor of the *American Journal of the Medical Sciences*. Dr. Kelly's death deprives the medical profession of one of its most promising pathologists and internists.

Edward Strong Bogert, M.D. Rear Admiral U. S. Navy, retired, died at the home of his daughter in New York City, February 16, aged 74. Dr. Bogert entered the Navy in June, 1861, served through the Civil War, and was on duty with Farragut's Squadron at the capture of New Orleans and the campaign of the Mississippi River; he was promoted to medical director, and was retired May 7, 1898. He was a graduate of the New York University Medical College in 1860, and a member of the Society of Bellevue Hospital Alumni.

William Henry McDonald, M.D. Bellevue Hospital Medical College, 1871; a member of the Colorado State Medical Society; a veteran of the Civil War, in which he served in both the Army and Navy; for twenty-four years resident physician at Pueblo for the American Smelting and Mining

Company, and surgeon for the Missouri Pacific and Santa Fe systems; died at his home in Pueblo, February 3, from chronic interstitial nephritis, aged 64.

George W. Osborne, M.D. Columbus (O.) Medical College, 1883; a member of the Ohio State Medical Association; died at his home in Dry Run, February 19, from paralysis, aged 58.

Charles Hamlin Phelps, M.D. Medical College of Ohio, Cincinnati, 1876; a member of the Ohio State Medical Association; president of the St. Mary's Board of Education; died suddenly at that place, February 21, aged 68.

Franklin J. Foster, M.D. Georgetown University, Washington, D. C., 1871; a veteran of the Civil War; and for twenty-five years an employee of the War Department; died at his home in Washington, February 5, from cerebral hemorrhage.

Joseph A. W. Hull, M.D. Medical College of Ohio, Cincinnati, 1880; died at his home in Stella, Neb., February 7, from hemorrhage of the stomach, aged 54.

Frederick Coggeshall, M.D. Harvard Medical School, 1892; a member of the American Medical Association, and American Academy of Medicine; a specialist in gynecology and neurology; a member of the neurologic staff of Boston Dispensary; formerly physician to the Boston Hospital and pathologist to Carney Hospital; died at his home in Boston, February 1, aged 50.

Thomas Markley Trego, M.D. College of Physicians and Surgeons, New York City, 1874; a member of the American Medical Association; attending physician to the Child's Hospital, St. Margaret's Home for Infants, and the Home for Aged Men, Albany; died at his home in Albany, N. Y., February 16, from pneumonia following a fall, aged 63.

Percy Duncan Littlejohn, M.D. Yale University, New Haven, 1897; a member of the Connecticut State Medical Society; and of the American Urological Association; first assistant to the chair of genitourinary surgery in the New York Post-Graduate Medical School; died at his home in New Haven, February 11, from heart disease, aged 36.

Albertus T. Ritter, M.D. Baltimore (Md.) Medical College, 1893; a member of the Medical Society of the State of Pennsylvania; physician to the Perry County Alms House, and the Tressler Orphans' Home; died at his home in Loysville, February 10, from the effects of an overdose of chloroform, aged 40.

Massillon Cassatt, M.D. Medical College of Ohio, Cincinnati, 1864; for many years a practitioner of Cincinnati; formerly a member of the American Medical Association; a life member of the Cincinnati Academy of Medicine; died in Jacksonville, Fla., January 5, from organic heart disease, aged 71.

David Marshall Devilbiss, M.D. University of Maryland, Baltimore, 1872; a member of the Medical and Chirurgical Faculty of Maryland; formerly health officer of Frederick County, and a member of the state senate in 1903; died at his home in Woodville, February 14, from nephritis, aged 66.

Benjamin T. Abbott, M.D. Jefferson Medical College, 1870; a member of the American Medical Association; president of the Cape May County and Ocean City, N. J., boards of education; died suddenly, February 17, in the Pennsylvania Railroad station, Ocean City, from cerebral hemorrhage, aged 67.

Henry Schmalhausen, M.D. Jefferson Medical College, 1867; a pioneer practitioner of Montana; a veteran of the Civil War; surgeon-major of the First Regiment, Mont., National Guard; a resident of Idaho since 1875; died at his home in Pony, recently, and was buried January 26.

Oscar F. Pile, M.D. College of Physicians and Surgeons, Chicago, 1888; a member of the American Medical Association, and Tri-State Medical Association; United States pension examiner; died at his home in Memphis, Mo., February 12, after an operation for duodenal ulcer, aged 52.

James Pickens Burke, M.D. University of Pennsylvania, Philadelphia, 1853; a member of the Medical Association of the State of Alabama; surgeon of a Mississippi regiment in the Confederate service during the Civil War; died at his home in Meridianville, February 12, aged 80.

George William Mahle, M.D. University of Maryland, School of Medicine, Baltimore, 1905; a member of the American Medical Association; on the staff of the Robert Garrett Hospital for Children, Baltimore; died at his home, February 20, from tuberculosis of the lungs, aged 29.

Robert Hamilton Phelps, M.D. Syracuse (N. Y.) University, 1894; a member of the American Medical Association; local surgeon at Norwich, N. Y., of the Delaware, Lackawanna and Western, and New York, Ontario and Western railways; died at his home, February 6, aged 41.

Charles Joseph Hamnett, M.D. Bellevue Hospital Medical College, 1865; formerly of Homestead, Pa.; a contract surgeon in the Army during the Civil War; died at the home of his daughter in Washington, Pa., February 3, from obstruction of the esophagus, aged 76.

Edwin D. Leidy, M.D. Jefferson Medical College, 1885; a member of the Medical Society of New Jersey; formerly medical examiner of the public schools of Flemington Borough and Raritan Township; died at his home in Flemington, February 17, aged 53.

Lloyd Alexander Craig, M.D. University of California, San Francisco, 1907; a member of the Medical Society of the State of California; resident physician at St. Mary's Hospital, San Francisco; died at the home of his brother in Oakland, February 7, aged 26.

John Loring Burnham, M.D. Dartmouth Medical School, Hanover, N. H., 1888; a member of the American Medical Association; formerly consulting physician to Elliot Hospital, Manchester, N. H.; died recently at his home in Las Cruces, N. M., aged 53.

William Palmer Chisholm, M.D. New York University Medical College, 1881; a member of the Massachusetts Medical Society; formerly consulting surgeon to Brockton City Hospital; died at the Insane Hospital, Taunton, Mass., February 16, aged 58.

William L. Egan, M.D. Tulane University, New Orleans, 1882; a member of the Louisiana State Medical Society; formerly a member of the Shreveport Board of Health; died at his home in that city, February 19, from heart disease, aged 55.

Thomas Tomelty, M.D. Rush Medical College, 1899; a member of the American Medical Association; for several years health officer of Vernon and Muskego, Wis.; died at his home in Big Bend, Wis., February 16, from pneumonia, aged 45.

Frederic Garvin Conger, M.D. Western Pennsylvania Medical College, Pittsburg, 1895; secretary of the board of pension examiners of Mondovi, Pa., died at the home of his sister-in-law, in Oakland, Pittsburg, January 31, aged 41.

James Youngs Tuthill, M.D. Bellevue Hospital Medical College, 1864; a member of the Medical Society of the State of New York; and Associated Physicians of Long Island; died at his home in Brooklyn, February 15, aged 69.

George Whitfield Ward, M.D. Bellevue Hospital Medical College, 1874; for many years a member of the staff of the Metropolitan Throat Hospital, New York City; died at his home in New York City, February 8, aged 60.

John H. Williamson, M.D. Jefferson Medical College, 1859; a member of the Medical Society of the State of North Carolina; died at his home near Rockingham, February 11, from heart disease, aged 82.

Clarence Howard Slightam, M.D. College of Physicians and Surgeons, Chicago, 1899; formerly of Eau Claire, Wis.; in charge of the Native Hospital, Juneau, Alaska; died in that city, recently, aged 34.

Robert H. McCamy, M.D. University of Pennsylvania, Philadelphia, 1879; for more than thirty years a practitioner of Kensington, Philadelphia; died at his home, January 5, aged 55.

Richard Asbury, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1865; for many years a practitioner of Monroe City, Mo.; died at his home in Hunter, Okla., January 19, aged 72.

Frank Orlando Webber, M.D. Harvard Medical School, Boston, 1877; a member of the Massachusetts Medical Society; died at his home in Cambridge, February 14, from pneumonia, aged 56.

Charles Franklin Kingsbury, M.D. Dartmouth Medical School, Hanover, N. H., 1856; a member of the Massachusetts Medical Society; died at his home in West Medford, February 14, aged 86.

Lafayette Summers, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1876; a member of the Iowa State Medical Society; died at his home in Milton, February 6, aged 61.

Charles Carroll McCaffrey, M.D. Eclectic Medical Institute, Cincinnati, 1908; of Huntington, W. Va.; died in Seton Hospital, Cincinnati, Dec. 21, 1910, from pneumonia, aged 36.

Orrel McFadden, M.D. Albany (N. Y.) Medical College, 1865; for forty-one years a practitioner of Massena, N. Y.; died at his home, Dec. 29, 1910, from nephritis, aged 74.

Alexander Franklin Binkley, M.D. Vanderbilt University, Nashville, Tenn., 1879; died suddenly at his home near Sycamore, Tenn., February 4, from acute gastritis, aged 66.

Adolph Kraemer, M.D. University of Zurich, Switzerland, 1894; a specialist on diseases of the eye; of San Diego, Cal.; died at his home in that city, January 24, aged 46.

David M. Miller, M.D. College of Physicians and Surgeons, Baltimore, 1887; died at his home in Indian Springs, Tenn., January 8, from disease of the kidneys, aged 69.

Daniel Franklin Royer, M.D. Jefferson Medical College, 1875; a practitioner of Orange, Cal., for twelve years; died Nov. 7, 1910, after an operation for appendicitis.

Theophilus N. Kirkpatrick, M.D. College of Physicians and Surgeons., Keokuk, Ia., 1872; died at his home in Letcher, S. Dak., Nov. 8, 1910, from diabetes, aged 61.

Andrew Niles, M.D. Philadelphia University of Medicine and Surgery, 1852; died in his apartment in Carbondale, Pa., January 17, from senile debility, aged 79.

James C. Wright, M.D. Medical College of Georgia, 1894; a member of the American Medical Association; died at his home in Folkston, January 2, aged 52.

Helen M. Miller, M.D. Woman's Medical College of Pennsylvania of Pennsylvania, Philadelphia, 1884; died at her home in Cleveland, January 6, aged 58.

Frank R. Wyroznski, M.D. Ensworth Medical College, St. Joseph, Mo., 1906; died at his home in St. Louis, February 6, from tuberculosis, aged 32.

Frank Moore Doyle, M.D. Western Pennsylvania Medical College, Pittsburg, 1897; died at his home in Pittsburg, February 7, aged 39.

Josiah M. Bosworth, M.D. Southern Medical College, Atlanta, 1887; died at his home in Atlanta, February 1, aged 69.

"The Propaganda for Reform"

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION.

PLANTOXINE

The Therapeutic and Commercial Possibilities in Milk Sugar

Some "patent medicines" are viciously fraudulent; others are simply fraudulent. Some contain habit-forming and dangerous drugs; others contain no drugs at all. Plantoxine is a nostrum marketed by the Plantoxine Company and we understand that the Plantoxine Company is really Edward W. Crittenden, a lawyer, who runs this business as a side line. The mere study of the advertising matter that accompanies Plantoxine would be sufficient to convince one that a lawyer had either written it or had very carefully "edited" it. Plantoxine is said to be:

> "A Preparation of Constitutional Medicines formulated as a Corrective in Abnormal Conditions of the System which create Undue Susceptibility to Miasmatic Diseases, Plant Pollen, La Grippe, etc.; Chronic Malarial Diseases; Hay Fever, Hay Asthma, Rose Cold, etc.; Influenza and La Grippe."

In a descriptive booklet on the nostrum, the theory is advanced that "hay fever and malaria are regional associates," and that both of these pathologic states "viciate [*sic*] the blood." We are further told that "hay fever and la grippe are recognized as different forms of influenza." Having evolved these theories, the "inventor" of Plantoxine set about to discover a cure—or, as it is cautiously designated, "a successful treatment"—for these related diseases.

> "After five years of diligent and painstaking effort along these lines such a remedy has been evolved."

The remedy, of course, is Plantoxine. Says the exploiter:

> "In Plantoxine we now have a simple preparation of the classical constitutional medicines, delicately proportioned and adapted to the general pathology of these cases. It is guaranteed under the Pure Food and Drugs Act of June 30, 1906. and therefore may be considered perfectly safe, while its effectiveness in individual cases may be left to be decided by practical tests."

Naturally, a preparation possessing the properties claimed for Plantoxine would be brought to the attention of physicians by their patients. It is not surprising, then, that the Association's laboratory has been asked to examine this preparation to determine whether or not it contained cocain or any other dangerous or habit-forming drugs. The report of the Association's chemists follows:

LABORATORY REPORT

"The specimen received was a white, odorless powder having the physical properties of milk sugar. Qualitative tests demonstrated the absence of cocain and other alkaloids and indicated that the substance was probably milk sugar. Some time later the correspondent, who had first written to the laboratory, sent an original package of Plantoxine for examination.

"Plantoxine is sold in packages each containing 40 powders, each powder containing about 2 grams (30 grains) of the preparation. The package, which retails for $1.00, contains about 2¾ ounces of the preparation.

"Quantitative examination indicated that Plantoxine consists entirely of milk sugar. The presence of medicinal substances could not be determined. If present their quantities must be small.

"In this connection it should be pointed out that the effect of cocain or its substitutes on the tongue furnishes a very sensitive and fairly distinctive test which may be used by physicians with advantage. If a trace of a powder, such as this, produces no benumbing effect when placed on the tongue the practical absence of cocain or its substitutes may be assured."

The story is told by Mr. Adams in "The Great American Fraud," that a general agent for a jobbing house once declared that he could put an article on the market, possessing neither remedial nor stimulant properties, and by skilful advertising persuade people that it had great therapeutic virtues. Challenged to a bet, he put out his "remedy," and within a year had won the wager. His preparation was nothing but sugar! In the light of the analysis just given, one wonders whether Mr. Crittenden—The Plantoxine Co.—also, is trying to win a bet. As this business has been conducted now about four years, it has ceased to be an experiment and is, presumably, on a paying basis.

The original boxes in which Plantoxine comes, give the price as 75 cents. These words have been obliterated and the preparation is now sold for $1. Doubtless, the advance is due to the increased cost of living—sugar probably costs more now than it did four years ago.

We must give Mr. Crittenden credit for at least a certain degree of modesty in the claims made for his discovery:

> "Plantoxine must not be expected to cure everything. Laxatives, lithia salts, calomel or other special treatment temporarily may be required, but it should be remembered that such measures are to be employed only when specially indicated and that they are not to be considered as being regularly associated with Plantoxine treatment."

Truly Mr. Adams was right when he said that "our national quality of commercial shrewdness fails us when we go into the open market to purchase relief from suffering." While, probably, it would be difficult to get the average, wide-awake American to purchase wooden nutmegs it seems to be an easy matter to sell milk sugar worth 10 cents a pound, wholesale, at $5.82 a pound, retail—providing it is sold as a "cure" for hay fever and "related diseases"!

Organic Iodin Preparations

Iodism is one of the serious disadvantages connected with the use of iodin. To obviate it various suggestions have been made but the combinations of iodids with other remedies designed to lessen their poisonous effects have failed to obviate the occurrence of iodism. This disadvantage of the iodids has led to the recommendation of numerous substitutes which are generally combinations of iodin with various organic radicals. The essential inadequacy of these preparations is emphasized by von Notthafft (*Monatsh. f. prakt. Dermat.*, Oct. 15, 1910, p. 343). He says: "Where iodism is indeed less frequently observed (in these cases indeed it is not wholly excluded), a more careful observation establishes the fact that the preparation either has other disadvantages or that the lower degree of toxicity has in fact its basis in a feebler activity; either the substitutes evolve too little iodin or they split it off with greater difficulty." This is true of substitutes for iodids in general, such as iodoform, iodol, iodolacid, iodipin, iodolenum, iodomeninum, iodopyrin, iodeigone, sajodin and others.

Iodival has a peculiar position. It is true that it produces less irritation of the stomach and intestine but symptoms on the part of the nervous system occur so much the more readily. According to Notthafft, this is to be regretted as the remedy is especially recommended for syphilis of the nervous system. Iothion has the disadvantage of producing cutaneous irritation, so that it cannot be used on sensitive skins. Notthafft reports his experiences with iodoglidin, a preparation in which iodin is combined with a nuclein-free, non-irritating vegetable albumin. The claim has been made that this preparation is free from objectionable side effects. Notthafft is of the impression that it is somewhat better tolerated than the iodids, although he cannot base this on absolute figures because, as is well known, the tolerance of the iodids varies extremely with different people. He finds, however, that it sometimes disagrees with the stomach and may produce serious iodism of which he reports two interesting cases. He sums up his opinion of iodoglidin as follows: It is in general an effective preparation in syphilis, although it acts somewhat more slowly than the iodids. It induces toxic effects somewhat less frequently: still acne, coryza, intestinal affections and nervous disturbances are not rarely observed. While it is a practicable remedy and while it may be tried in certain cases in which other iodin preparations are not borne, and might have a field for application in cases in which the body should contain little salt, still the unlimited praise which it receives in certain circulars and abstracts cannot be accepted. Notthafft cannot agree with the opinion of Seifert and Imhoff that it is tasteless. On the contrary it possesses a somewhat sharp taste resembling mustard oil which is disagreeable to many persons. The claim of Zieler that it produces iodism only in persons with marked idiosyncrasy must be expressly denied.

It is evident from these observations that the claims made for substitutes for the ordinary preparations of iodin should not be accepted without critical examination.

Green Extracts

Green extracts or tinctures of fresh herbs have been introduced into pharmaceutical practice on the theory that they would possess therapeutic properties which would be dissipated by drying the herbs. This may possibly be true of a few plants but for the most part, especially for plants which contain non-volatile, active constituents, the plan is not a good one on account of the variable amount of water contained in the fresh plant. These extracts are official in the British Pharmacopeia and a general formula for tinctures of fresh herbs is included in the United States Pharmacopeia. The following from the *British and Colonial Druggist*, Jan. 20, 1911, shows the unreliability of these preparations:

> Noteworthy among a large number of interesting points in the nineteenth annual laboratory report of Messrs. Southall Bros. and Barclay, Limited, are some observations on the green extracts of the B. P., which have again manifested their unreliability and variation in strength. Evidence of this is given by the following figures of total alkaloids in the green belladonna extract prepared from the herb of the last nine seasons:
>
> | | | |
> |---|---|---|
> | 1.38 per cent. | 0.87 per cent. | 1.57 per cent. |
> | 1.50 per cent. | 1.04 per cent. | 0.98 per cent. |
> | 1.08 per cent. | 1.25 per cent. | 0.80 per cent. |
>
> Thus, the extract of the last season was little more than a half the strength of that of 1908. Worse still, a sample obtained recently of undoubted purity gave only *0.73 per cent.* And again, as regards hyoscyamus, the total alkaloid yielded by a bulk sample of last season's manufacture was 0.084 per cent.—a very low figure. These poor results may perhaps be traced to the wet season, but, having regard to the fluctuations indicated, the view that the green extracts will not survive the present edition of the Pharmacopeia is likely to be confirmed by the event. If they should be retained it appears to be very desirable that standards of alkaloidal strength should be fixed.

As extracts of green drugs in times past have frequently been shown to be variable and unreliable, the observations noted above form another link in the chain of evidence condemning such preparations.

While the formula in the United States Pharmacopeia for the preparation of green tinctures is a general one, the consideration of the facts cited, is recommended to the committee now engaged in revising the Pharmacopeia.

Association News

CENTRAL ROUTES TO LOS ANGELES

More Details of Railroad Plans for the Trip to the Next Session of the American Medical Association

The next annual session of the American Medical Association will be held in Los Angeles, Cal., June 27-30, 1911. Several announcements have appeared in The Journal: A list of hotels with rates was published February 18, page 527; the railroad rates from the Mississippi Valley were announced February 18, page 528; a preliminary announcement of the entertainments was given February 25, page 605. There will be a special convention issue of The Journal as usual in May, giving the program and full particulars; in the meantime various items of information will be given from week to week. The Transportation Committee has submitted the following:

CENTRAL ROUTES TO THE LOS ANGELES SESSION

Last week attention was called to the American Medical Special to Los Angeles over the Santa Fe and the reasons were given for selecting this route. This week, we call attention to the central routes and the points of interest along the following lines:

There are several excellent roads out of Chicago, among which may be mentioned the Burlington, the Rock Island, the Northwestern, the Chicago, Milwaukee and St.Paul, the Illinois Central and the Chicago and Great Western. Most of these lines run magnificent trains through to California. One may go by way of Denver, Salt Lake City and San Francisco to Los Angeles or take the short line from Salt Lake City directly to Los Angeles.

From Denver one may go south through Colorado or by the Denver and Rio Grande to Salt Lake City. On the Denver and Rio Grande is perhaps the most beautiful mountain scenery in this country. Salt Lake City is well worth seeing as is Salt Lake itself which is crossed by the train. West of Salt Lake on the Southern Pacific or Western Pacific one crosses the Great American Desert, then over the Sierra Nevada mountains to San Francisco and down through California to Los Angeles.

From Salt Lake City one may go by the San Pedro, Los Angeles and Salt Lake line directly to Los Angeles. This is the shortest route from Salt Lake City to Los Angeles and crosses a mountainous and desert country. Or one may go from Chicago to Omaha, then over the Union Pacific to Ogden and from there to San Francisco and then down to Los Angeles.

The fare over any of these routes is the same, namely $62.50 for the round trip from Chicago. This rate applies if one goes by any one of these routes and returns by the same or by any other of them; or if one goes by one of them and returns by a southern route; or vice versa. To go by any one of them and to return by one of the northern routes an additional fare of $15.00 will be charged. One cannot both go and return by one of the northern routes at the rates here quoted.

The time by all of the central routes is practically the same, namely, about three days unless stops are made on the way.

Details of the northern routes will be published next week; and later accounts of special trains will be given.

M. L. Harris, Chicago,
Chairman of the Committee on Transportation.

Correspondence

Danger of Trichinosis from Pork

To the Editor:—From time to time reports of outbreaks of trichinosis reach the Department of Agriculture, affording indisputable evidence that the extremely unhygienic custom of eating raw or imperfectly cooked pork is followed to some extent in the United States. On account of the danger involved in this custom, and on account of the common belief by persons aware of the existence of such a disease that pork inspected and passed under the federal meat-inspection law has been inspected for trichinæ, the Department of Agriculture has issued the following notice:

COOK PORK WELL

Cases of illness sometimes occur from eating uncooked or insufficiently cooked pork which is infested with a microscopic parasite commonly known as trichina or flesh-worm, the scientific name being *Trichinella spiralis.* An average of 1 or 2 per cent. of the hogs slaughtered in the United States are infested with this parasite. When transmitted to human beings, trichinæ may cause serious illness, sometimes resulting in death. Out of about 15,000 cases of trichinosis recorded in medical literature, most of which occurred in Europe, 830 resulted fatally.

No method of inspection has yet been devised by which the presence or absence of trichinæ in pork can be determined with certainty, and the government meat inspection does not include inspection for this parasite. All persons are accordingly warned by the United States Department of Agriculture not to eat pork, or sausage containing pork, whether or not it has been inspected by federal, state or municipal authorities, until after it has been properly cooked.

A temperature of about 160° F. kills the parasite; therefore pork when properly cooked may be eaten without any danger of infection. Fresh pork should be cooked until it becomes white and is no longer red in color in all portions of the piece, at the center as well as near the surface Dry salt pork, pickled pork, and smoked pork previously salted or pickled, providing the curing is thorough, are practically safe so far as trichinosis is concerned, but, as the thoroughness of the curing is not always certain, such meat should also be cooked before it is eaten.

A pamphlet giving information on the subject may be obtained on application to the Secretary of Agriculture, Washington, D. C.

I desire to ask the cooperation of the medical profession in giving publicity to the fact that pork in its raw state is a dangerous article of diet, and would also request that any cases of trichinosis which may come under the care of readers of this article be reported to this bureau. The information especially desired is the number of cases and of fatalities, date and place of occurrence of the outbreak, nationality of the patients, and source of the pork which caused the outbreak.

A. D. Melvin, Washington, D. C.
Chief of the Bureau of Animal Industry, United States Department of Agriculture.

Anesthetic vs. Carbon Dioxid

To the Editor:—I have read with interest your editorial on "The New Theory of Shock," in The Journal, Feb. 11, 1911, page 424.

In 1896, I was the guest of the Neurological Society of London, when Mr. Waller demonstrated the effects of anesthetics on peripheral nerves. He showed that ether was the safest anesthetic and that it was better combined with carbon dioxid, as then the nerve showed more rapid response to electrical stimulation. When chloroform alone was used he showed that the peripheral nerves would not respond to electrical stimulation but that when the chloroform was mixed with carbon dioxid they readily responded to electricity and returned to normal. Ever since then, when I administer chloroform I give a little of the drug but keep my hand over the mask, thus making the patient inhale his own breath, in this way giving a certain amount of carbon dioxid.

I have always had good results with this method of anesthesia. Once I was present at an operation when the patient stopped breathing; she was resuscitated and the operation carried to a successful conclusion by administration of chloroform plus rebreathed air—carbon dioxid. In December, 1901, a colleague had a chloroform fatality in a patient with nephritis, and as I had recently had personal experience with nitrous oxid-ether anesthesia, I advocated its adoption in this case; thereby I had the honor to introduce this form of anesthesia into Cincinnati with the original Bennett apparatus. This has been used continuously since at the Ophthalmic Hospital with satisfaction and success. Here, again, we have the carbon dioxid factor for the nitrous oxid only starts the anesthesia and then comes the ether, and by the closed rubber bag we again have the patient breathe carbon dioxid.

Your editorial explains Mr. Waller's demonstration of 1896 which showed that anesthetic plus carbon dioxid is safer than anesthetic alone, and that ether plus carbon dioxid is safer than chloroform in any combination.

W. Edwards Schenck, M.D., Cincinnati.

One Physician's Method of Increasing His Income

To the Editor:—I wish to contribute a statement to the subject of the remuneration of physicians:

I have been in the general practice of medicine since 1890 in Detroit on the same lot on which I was born. For twenty years I trusted all applicants for medical aid with results approximately as follows:

2 per cent. would pay me promptly.
13 per cent. could pay me only "when I went after them."
25 per cent. got out of paying me in every possible way.
60 per cent. did not pay me at all.

Jan. 1, 1910, I turned over a new leaf, and referred to other physicians all would-be patients who did not pay cash and had not approved credit. In 1910, the income from my practice was 98 per cent. greater than my average yearly income for the preceding twenty years and my expenses for 1910 were less than the average yearly expenses for the same period. Except for the fact that I gave my individual attention to my invalid mother for the three years prior to 1908, which cut into my practice considerably, I am unable to assign any other cause than this change of policy for the increase in income.

Since Jan. 1, 1910, I have had more time for reading, refreshment and sleep; and my present plan is preferable to that of those physicians whose ambition is to have the "largest practice" in a community at the cost of poor health or an early death.

John L. Irwin, M.D., Detroit.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

FRENKEL'S REEDUCATIVE MOVEMENTS

To the Editor:—Kindly give me some information about Frenkel's exercises. On page 453 of The Journal, of February 11, are references to them, and I would like to know the method of using these exercises.

E. A.

To the Editor:—In the abstract of an article on locomotor ataxia by Dr. Billings, I notice his recommendation of Frenkel's reeducation movements. What are these procedures?

Dr. C. F. Boucek, Allegheny, Pa

Answer.—References to the principal articles dealing with the reeducation of the muscles in tabes dorsalis by the method of Frenkel are given in The Journal, July 18, 1908, p. 239. An abstract of one of Frenkel's articles is given in The Journal, July 22, 1905, p. 294. Some account of the treatment is given in various books on the practice of medicine, and in a recent article by J. K. Mitchell, "Treatment of Locomotor Ataxia by Exercises of Precision," in the *Old Dominion Journal of Medicine and Surgery,* June, 1909; this article was abstracted in The Journal, July 10, 1909, p. 149.

The principle of the method is that while the lesions of tabes cannot be affected by treatment, the lost coordination can be more or less completely restored. This treatment consists in a psychic training of the powers of coordination, not in the attempt to increase muscular power, which often is not impaired. For this reason, the fatigue which may interfere with coordination is a nervous phenomenon, and should not be increased by having the patient attempt severe exercise. Patients with tabes do not feel fatigue readily, but indicate it by loss of precision in their movements, increase in pulse-rate, etc. The patient must be watched lest he go too far, but also should be encouraged to undertake movements of which at first he may not deem himself capable. One of Frenkel's exercises is to have the patient lie in bed and try to place his heel in a set of cup-like depressions in a board placed across the foot of the bed. In other instances, definite spaces are marked on the floor and he is directed to take steps that will bring the heel on each mark.

Precision in each exercise is insisted on by Mitchell, who says: "The exercises, from the simplest to the most complicated, must be performed accurately, with the idea always before both teacher *and pupil that* to do the prescribed movements correctly and *exactly is the task*—not just to do it. If the patient walks, he walks not to reach a certain spot, but to walk in a certain fashion. Individual teaching is absolutely required in the beginning. After the first lessons, and when the patient is once able to do a little work on his feet, he may join a class and find not only that the stimulus of competition is a help, but that his observation of the errors of others assists him to correct his own."

The exercises should not cause fatigue. As a rule, twice a day and not longer than from five to fifteen minutes at a time, and in the severer cases not longer than two or three minutes, should be the limit. Improvement is said to follow in every case, but the amount depends on the length of treatment rather than on the degree of incoordination. Several months are generally necessary if the patient is not to fall back into his old habits. Even the severest cases, if uncomplicated, give a good prognosis with persevering treatment Some of Frenkel's patients, with complete loss of the power of standing or walking, had these faculties entirely restored after from six to twelve months of treatment Orthopedic apparatus may be needed in some cases. Uibeleisen utilizes the buoyancy of water to help in the exercises, as described in The Journal, Jan. 14, 1911, page 162.

FIBROLYSIN IN OPHTHALMOLOGY

To the Editor:—1. With what success has fibrolysin been used in corneal ulcer?

2. What is the dosage used either as instillation into the conjunctival sac or as subcutaneous injection?

B. L. Schuster, Port Huron, Mich.

Answer.—According to "New and Nonofficial Remedies" and Wood's "System of Ophthalmic Therapeutics," fibrolysin is the trade name for a sterile solution of thiosinamin and sodium salicylate, and contains about 15 per cent. of the double salt. It is used as a substitute for thiosinamin. As it readily decomposes on exposure to the air it is commonly marketed in ampullas (Merck), or in bottles containing one dose only, to be given subcutaneously. A hypodermic injection of this remedy is more quickly absorbed, causes less pain and is more efficacious than thiosinamin alone. The remedy is rarely or never used for ulcer of the cornea, but is almost invariably prescribed for the scars remaining after the ulcers have healed. Its effect on any of these lesions is of little account unless used hypodermically or subconjunctivally; even then the remedy is of doubtful utility. Brandenburg has also tried the preparation in the form of intramuscular injections in corneal opacity following keratitis scrofulosa, keratitis purulenta, keratitis trachomatosa, in chronic uveitis and chronic retrobulbar neuritis.

2. Pick has prescribed a subconjunctival injection of 0.5 c.c. of a solution of 2 gm of thiosinamin in 20 gm. of water and 4 gm. of glycerin, corresponding to 0.45 gm. of fibrolysin (1/5 of an ampulla) once a week.

GALL-STONE FAKE

To the Editor:—Several months ago The Journal exposed a gall-stone fake, whereby the patient who took the "treatment" passed a quantity of "gall-stones" or, rather, "soap-stones." A person whom I know took a similar "treatment" and passed 125 soft gall-stones (some as large as hazel-nuts). One of my patients, who is suffering from acute gastritis, was requested to try the gall-stone remedy. I want to locate the article to show him how the fake works. If you can tell me the number of The Journal which contains this article I will be obliged to you. C. O. Nelms, M.D., Herscher, Ill.

Answer.—The "fake gall-stone trick" has been worked for some years by traveling fakers and more recently has been adapted to the "patent medicine" industry. In The Journal, Sept. 24, 1910, "Fruitola," one of the most widely advertised of the gall-stone cure fakes, was exposed, and this, doubtless, is the nostrum to which our correspondent refers. The analyses made by the Association's chemists indicated that Fruitola consisted essentially of anise-flavored olive oil and seidlitz powders.

GASOLINE FOR REMOVAL OF ADHESIVE PLASTER, ETC.

To the Editor:—Recent articles in The Journal make it a matter of conscience with me to announce that gasoline is the best solvent for the face of surgeon's adhesive plaster. The liquid should be freely applied with a wad of cotton. The plaster may then be removed without violence or depilation. So effectual is the solvent that the surgeon will not care whether the cementing material does or does not come away with the cloth. It is merely a matter of a few wads of cotton more or less.

In this connection, I wish to say that gasoline is an antiseptic and that it further commends itself by its power of removing machine-grease from injured fingers and of dissolving ointments at later dressings. Nothing in my office is so useful, with the sole exception of my ledger. Polished instruments, thoroughly dried, will not rust after receiving a dash of gasoline. When desired, one may use it as a solvent for paraffin and coat any instrument with a film. A few drops poured on the water in the wash-bowl will enormously increase the detergent power of soap and water and will prevent the deposit of smeary curds on the side of the bowl, even when hard water is used. A discreet use of it on the front of the doctor's coat and waistcoat will often exalt his personal pulchritude. Gasoline will clean up the bearings of the bicycle or centrifuge and will quickly remove all gum from the doctor's type-writer—or her writing-machine.

A liquid so inflammable should not be exposed in quantity. An ordinary oil-can is a fine dispensing apparatus, but a screw-cap bottle, such as the perfumers use for toilet waters, is much more elegant. I myself use a bottle that I got from my own wife—to avoid explosion. Dan Millikin, M.D., Hamilton, Ohio.

To the Editor:—The articles of Drs. Beardsley and J. Scott Brown, in The Journal, January 28 and February 25, respectively, concerning the removal of adhesive plaster, are of general practical interest. The costliness of Dr. Beardsley's oil of wintergreen and the pain and friction required in Dr. Brown's method with ether cause me to suggest the use of gasoline for the removal of the plaster. For a number of years I have used gasoline in the following manner: Saturate a cotton sponge with gasoline and apply it directly to the posterior surface and the end of the adhesive plaster. This loosens the end effectively and allows it to be grasped by a pair of thumb forceps. Then, by gentle traction on the end of the plaster, it is lifted away from the surface, and by applying the cotton sponge at the junction of the skin and remaining plaster the plaster is easily and rapidly peeled off. If any of the adhesive material remains it is quickly dissolved and removed by gentle friction with the aforesaid sponge.

J. A. Cannon, M.D., Washington, D. C.

THE WORD APPENDICEALGIA

To the Editor:—Who was the author of the new word "appendicealgia?" Has anything been published on the subject? What are the symptoms of the disease? A. C. J.

Answer.—The word appears in Dorland's "Medical Dictionary," as also does the abbreviated form "appendalgia." We do not know its author. Both are merely terms for appendicular colic, and as such they are treated in practically all works on appendicitis.

THE BRACHIAL PLEXUS

To the Editor:—Does the second thoracic nerve have anything to do with the formation of the brachial plexus nerve normally?

L. S. Griffin, M.D., St. Louis.

Answer.—Yes.

The Public Service

Medical Department, U. S. Army

Changes for the week ended Feb. 25, 1911.

Norman, Seaton, M.R.C., on his relief from temporary duty at Fort Wingate, N. Mex., ordered to Fort Bliss, Texas, for temporary duty.

Farrow, Edgar J., M.R.C., left Fort Morgan, Ala., en route to Fort Sam Houston, Texas, for temporary duty.

Wolven, F. Homer, D.S., left Fort George Wright, Wash., en route to Boise Barracks, Idaho, for temporary duty.

Freeman, Paul L., captain, left Fort Riley, Kan., for temporary field duty in Texas.

Ferenbaugh, Thomas L., lieut., left Fort Des Moines, Iowa, for temporary duty in field in Texas.

Powell, William A., captain, ordered to the Presidio of San Francisco for duty.

Thomason, Harry D., captain, ordered to proceed at the proper time to Frankfort, Ky., for conference about Feb. 26, 1911, with the adjutant of Kentucky in connection with reorganization of the sanitary troops in that state.

Schlanser, A. E., lieut., left Walter Reed General Hospital, Takoma Park, D. C., en route to West Point, N. Y., for temporary duty.

Johnson, Thomas H., lieut., left Fort Baker, Cal., en route to Fort Barry, Cal., for temporary duty.

Dickenson, C. F., M.R.C., left Fort Barry, Cal., on ten days' leave of absence.

Pillsbury, Henry C., captain, left Jefferson Barracks, Mo., with recruits en route to Fort McDowell, Cal.

Phalen, James M., captain, left Columbus Barracks, Ohio, with recruits en route to Fort McDowell, Cal.

Allen, William H., lieut., left Fort Slocum, N. Y., with recruits en route to Fort McDowell, Cal.

Patterson, Edwin W., M.R.C., granted leave of absence for three months, with *permission to go beyond the seas, to take effect on* his relief from duty in the Philippines division.

Lynch, Charles, major, order directing him to proceed to the Philippine Islands for duty is revoked.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

OPTOMETRY EXAMINATION QUESTIONS

Since 1901, laws creating state boards for the examination of practitioners in "optometry" have been adopted in twenty-four states. These are: Minnesota (1901), California and North Dakota (1903), Oregon (1905), New Mexico (1906), Arizona, Montana, Idaho, Utah, Tennessee, Indiana and Nebraska (1907), New York, Vermont, West Virginia, North Carolina, Delaware, Maine, Washington, Iowa, Rhode Island, Kansas, Michigan and Florida (1909).

Many physicians are apparently indifferent to this invasion of the field of medicine, and regard these self-styled "optometrists" as merely spectacle fitters. As an evidence of the extent to which they are endeavoring to cover the entire realm of the diseases of the eye, the examination questions used by the boards in a number of states are quoted herewith. As will be seen, the questions relate, not only to the correction of errors of refraction, but to practically all diseases of the eye. The questions given are quoted verbatim from the examination papers.

California.—Explain the following: Aberration, Aniridia, Actinic, Steigmatism, Cyclophoria, Dacryoma, Erucleation, Epicanthus, Senopia, Epilation, Caruncle, Myosis, Mydriasis, Cycloplegia, Chromatism, Nyctalopia, Keratitis, Leucoma, Hordeolum, Anisometropia, Ontimetropea. Describe the dilator iris, its function and nerves. Name the principal arteries of the eye. State shortly what you know of cataract diagnosis, its varieties, cause and methods of removal.

North Dakota.—What is blepharitis marginalis? Describe the difference between hordeolum and chalazion. Describe simple corneal ulcer, giving etiology and prognosis. Describe cataract in general and one kind or more in particular. Describe glaucoma. What are the objective symptoms? Describe emblyopia potatorum. How does the retina appear in a bad case of aluminuria?

Arizona.—What is blepharitis? If neglected, is it likely to become a permanent trouble? What is granular ophthalmia? What is conjunctivitis? What is iritis? What is glaucoma? What is choroiditis? Symptoms? What is apt to be the effect of rupture of the choroid?

Utah.—What is pterygium? trachoma? How would you detect cataract? What is it? What is nystagmus; anisometropia?

Oregon.—What is a cataract? How do you tell whether a patient has cataract or not? What is glaucoma and what are some of the most common symptoms? What is the choride and what are its uses? What is amaurosis? What does the motor oculi or third pair of nerves supply? What is cyclitis? What is the conjunctiva and what are its uses? What is the least and the most sensitive part of the retina and why? What are the lavator palpebræ and what are its uses?

Indiana.—What do you understand by the term homonymous hemianopsia? Describe the difference between the location of a ptergium and a cataract. Tell how to differentiate between a paralysis of an external muscle and a concomitant squint. What is a pupillary reflex? How would you examine the eyes to determine the pupillary action? Describe the action of an Argyll-Robertson pupil. How many layers has the retina? Name the most sensitive part of the retina. Describe the optic disk. From what source does the retina obtain its nourishment? Name the bones of the orbit. Describe the muscles of the eyelids. Where situated and what is the iris? Give its function. Name the humors of the eye. Describe the optic track from the eye to the optic thalamus.

Iowa.—What nerves supply the two muscles controlling the iris? Describe a cataract and tell what you know of the different kinds. What is keratitis? What is blepharitis? How does the ciliary muscle affect vision? How would paralysis of the fourth cranial nerve affect the eyes? How does the liver influence digestion? What are the functions of the thyroid gland?

Given a patient complaining of short periods of dimness of both near and distant vision, which are becoming more frequent, with occasional instants of complete darkness; these periods sometimes accompanied by pain in eyeball and orbital region; also states that during these periods halos are seen around the lamp or similar spots of light; that he has never worn glasses for distance, but that of late he has been compelled to change his reading glasses to higher and higher power at frequent intervals. On examination you discover a "hazy" appearance of the cornea, pupil dilated, and immobile or at least sluggish of response, and on pulsating the eyeball you discover an abnormally high tension, what would you diagnose this case to be?

What is the generally accepted theory as to its cause? What is meant by the term monocular diplopia, and what is usually indicated by it? Describe briefly arcus senilis. Define cataract, giving symptoms, and tests you use when you suspect its presence. Describe pterygium. What is a chalazion? What is a stye? What is trachoma? What is meant by scotoma?

Delaware.—Describe a cataract and tell what you know of the different kinds. What is blepharitis marginalis? Describe simple corneal ulcer and give the most conspicuous symptom. Name a disease of the eyes on account of which emigrants are refused admission to this country; give reason. Describe glaucoma and give the principal diagnostic features. What is hemniopa and its cause? What are the rods and cones and their function?

Rhode Island.—Describe cataract in general and some one particular kind fully. What is choroiditis, retinitis, iritis, conjunctivitis, blepharitis marginalis? Describe simple corneal ulcer and give the most conspicuous symptom. Describe glaucoma and give the principal diagnostic feature.

Maine has as yet held no examinations. The secretary of the Maine Board of Optometry, however, announces that the subjects for examination will be: Practical Optometry, Practical Optics, Physiological Optics, Theoretic Optometry, Anatomy and Physiology, Diseases of the Eye.

The Vermont, 1909, Handbook on Optometry announces the following subjects for the examination in Montpelier, January, 1910: Theoretic Optics, Practical Optics, Objective Optometry, Subjective Optometry, Anatomy and Physiology of the Eye, Physiologic Optics, Pathologic Conditions of the Eye.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Eighth Month—First Weekly Meeting

General Subject for the Month: Non-Inflammatory Diseases of the Uterus and Appendages

ANATOMY

UTERUS: Shape, size, position, important relations. Broad, round and uterosacral ligaments. Portions of uterus. Structure; serous, muscular and mucous coats. Attachments of vagina to cervix. Blood-vessels and nerves. Lymphatics, three groups.

FALLOPIAN TUBES: Position, portions, structure. Blood-supply. Broad ligament, structure, relations, contents.

OVARY: Shape, size, position, relations, ligaments. Structure and functions. Blood-vessels, nerves, lymphatics.

PELVIC FLOOR: Skin, superficial and deep fascias, levator ani, transverse perineal, ischiocavernosi and sphincter ani muscles. Functions and mechanism of pelvic floor.

DISPLACEMENTS OF THE UTERUS

ASCENT, descent, lateral, anterior and posterior, flexion and version.

PROLAPSE: Pathology: Degrees of prolapse, changes in uterus, in adjacent organs.
Diagnosis. Symptoms, physical examination.

ANTEFLEXION: Incidence, causes.
Symptoms. Dysmenorrhea, sterility, leukorrhea.
Treatment.

RETRODISPLACEMENTS, VERSION AND FLEXION

CAUSES: Injury to pelvic floor, subinvolution of uterus, too long on back after labor, overdistended bladder and rectum, dress, occupation, posture, chronic disease, etc.

SYMPTOMS: Backache, leukorrhea, headache, pelvic, rectal and bladder symptoms, menstrual disorders, nervous symptoms.

TREATMENT: Removal of cause. Replacement. Use of pessary and tampon. Operative treatment: Technic of shortening round ligaments, Montgomery, Barrett, Gilliam operations.

INVERSION OF THE UTERUS

Acute and chronic inversion. Symptoms. Treatment.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

CONNECTICUT: Regular, City Hall, New Haven, March 14-15. Sec., Dr. Charles A. Tuttle; Homeopathic, Grace Hospital, New Haven, March 14. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.; Eclectic, Hotel Garde, New Haven, March 14. Sec., Dr. T. S. Hodge, 19 Main St., Torrington.

MAINE: Portland, March 14-15. Sec., Dr. F. W. Searle, 806 Congress St.

MASSACHUSETTS: State House, Boston, March 14-16. Sec., Dr. Edwin B. Harvey, Room 159, State House.

WYOMING: Laramie, March 7-9. Sec., Dr. J. B. Tyrrell.

Illinois July and October Reports

Dr. J. A. Egan, secretary of the Illinois State Board of Health, reports the written examinations held at Chicago, July 20-22, and October 19-21, 1910. The number of subjects examined in was 16; total number of questions asked, 100; percentage required to pass, 75.

At the examination held July 20-22, the total number of candidates examined was 145 of whom 117 passed and 26 failed. Two candidates did not complete the examination. The following colleges were represented:

College	Year Grad.	Total No. Examined.
PASSED		
Denver and Gross College of Medicine	(1908)	1
Georgetown University	(1909)	1
George Washington University	(1909)	1
Bennett Medical College, Chicago	(1910)	10
Chicago College of Medicine and Surgery	(1910)	15
Hahnemann Medical College and Hospital, Chicago	(2, 1909) (2, 1910)	4
Hering Medical College	(1910)	1
Jenner Medical College	(1910)	9
Illinois Medical College	(1910)	2
Northwestern University Med School	(1909) (8, 1910)	9
College of Physicians and Surgeons, Chicago	(1909) (16, 1910)	17
Reliance Medical College	(1910)	4
Rush Medical College	(1899) (1909) (11, 1910)	13
University of Louisville	(1910)	12
Tulane University of Louisiana	(1903)	1
University of Michigan, Homeopathic College	(1910)	1
Homeopathic Medical College of Missouri	(1908)	1
St. Louis College of Phys. and Surgs.	(1906) (4, 1910)	5
Barnes Medical College	(1910)	3
Jefferson Medical College	(1910)	3
Vanderbilt University	(1910)	1
McGill University, Quebec	(1910)	2
University of Athens, Greece	(1901)	1
FAILED		
University of Arkansas	(1909)	1
Bennett Medical College, Chicago	(1909) (2, 1910)	3
Chicago College of Medicine and Surgery	(1910)	2
College of Medicine and Surgery, Physio-Medical, Chicago	(1910)	1
Hering Medical College	(1910)	1
Illinois Medical College	(1910)	1
National Medical University, Chicago	(1909)	2
College of Physicians and Surgeons, Chicago	(1910)	2
Keokuk Medical College, College of Physicians and Surgeons	(1908)	1
Sioux City College of Medicine	(1906)	1
Hospital College of Medicine, Louisville	(1904)	1
Barnes Medical College	(1910)	2
St. Louis College of Physicians and Surgeons	(1906) (1908) (3, 1910)	5
Meharry Medical College	(1910)	2
University of Naples, Italy	(1901)	1

At the examination held October 19-21, the total number of candidates examined was 81, of whom 34 passed and 42 failed. Five candidates did not complete the examination. The following colleges were represented:

College	Year Grad.	Total No. Examined.
PASSED		
Bennett Medical College	(1910)	2

University of Athens, Greece	(1903)	55

Book Notices

Pellagra. By Dr. A. Marie, Physician to the Asylums, Department of the Seine, Paris, France. With Introductory Notes by Professor Lombroso. Authorized Translation from the French by C. H. Lavinder, M.D., Passed Assistant Surgeon U. S. P. H. and M.-H. Service, and J. W. Babcock, M.D., Physician and Superintendent State Hospital for the Insane, Columbia, S. C. Cloth. Price, $2.50. Pp. 434, with illustrations. Columbia: The State Co., 1910.

The sociologic and economic importance of pellagra and the still unsolved mystery of its etiology are sufficient to ensure a welcome to any work presenting a good review of the subject. The comparative newness of the subject to the profession in the United States makes the preparation of such a book an unusually difficult task for an American physician. The authors, therefore, decided to present to English readers an authorized translation of the standard work of Marie, adapting it to American conditions by extensive additions and explanations. They were fortunate in securing the friendly interest of Lombroso, who shortly before his death wrote a preface for the work. The work of Marie is essentially an abbreviation of the larger work of Lombroso, so that the translators, in order to give a wider view of the etiologic theories, have introduced an account of the views of the antizeists. A chapter on symptomatology is also the work of the translators, so that the contributions to this work from their hands form an important feature of the book. The views on etiology are primarily those of Lombroso and connect the disease in some way with spoiled maize. The discussion of prophylaxis follows the same course as a necessary corollary. In this respect the European origin of the book necessitates a certain lack of adaptability to American conditions. The account of European varieties of maize and the methods of culture are of minor interest to the American farmer and sanitarian. The problems in this country concern more particularly the harvesting of unripe corn and the transportation of damaged or adulterated meal.

The authors give the conclusions and suggestions of Alsberg on the relations of corn culture in the United States to pellagra, but further study of this subject would be desirable. The account of symptomatology, diagnosis, prognosis and treatment is sufficiently complete. Two bibliographies, one English and the other foreign are appended. These are arranged chronologically and show the very considerably increased interest in the subject in the last few years, especially in the United States. The illustrations are mostly pictures of pellagrins, mostly Americans.

In general, the work may be unhesitatingly commended as a good presentation of this important subject.

The Practice of Surgery. By James G. Mumford, M.D., Visiting Surgeon to the Massachusetts General Hospital. Cloth. Price, $7 net. Pp. 1015, with 682 illustrations. Philadelphia: W. B. Saunders Co., 1910.

This book is novel in the manner of its conception and in being a text-book for the graduate who has surgical aspirations and not for the student. It is a text-book on clinical surgery. The principles of surgery are not considered, and preliminary training in pathology, bacteriology and the principles of surgery is presumed. Mumford narrates his experiences with surgical operations extending over a considerable number of years, describing what, in his opinion, are the best procedures to adopt for a given case. Useless gossip and verbose descriptions of every known procedure, good, bad or indifferent, are wisely omitted. The book cannot fail to prove really useful to anyone who is looking for light in this field.

Surgical diseases are taken up in the order of their interest, importance and frequency, the sequence followed being, first, appendicitis; then surgical diseases of the abdomen and its contents, of female organs of generation, of the genito-urinary organs, of the chest, face and neck, of the head and spine; and minor surgery with diseases of structure. In the treatment of appendicitis the author prefers the muscle-splitting operation; he advocates removing the appendix (after the abdomen is opened for other reasons) if there is cause to suspect that it may become involved through the subsequent spread of peritoneal inflammation and the formation of adhesions about it. This is one of the few instances in which the author has allowed himself to indulge in an excursion into the field of debatable problems. Controversial points, such as the relative merits of cholecystostomy and cholecystectomy, are discussed briefly but pointedly, and the reader receives practical, dependable information on the subject.

One of the especially good features of the book is that the general cardinal principles for operation—gall-bladder operations, for instance—are stated, and then the special indications for performing a particular operation—as cholecystostomy or cholecystectomy—are given. The author has displayed unusually good judgment in his selection of operations. Every detail of surgical progress has been noted, applied, accepted if good and rejected if worthless.

The illustrations are excellent, numerous and helpful; they are elucidating and not confusing.

The Diseases of Infants and Children. By Edmund Cautley, M.D., Cantab., Senior Physician to the Belgrave Hospital for Children. Cloth. Price, $7 net. Pp. 1042. New York: Paul B. Hoeber, 69 East 59th Street, 1910.

Many new books on diseases of children have appeared in the last few years, and English writers have made three notable contributions. The books of Thompson and of Still made no attempt at completeness; they dealt at great length with things in which the authors were especially interested, and entirely passed over equally important subjects. Thus, while they are of value to the practicing physician, they cannot be considered as text-books. Cautley felt that "a new, systematic and up-to-date book on the subject was required," and the present volume is the result. This book is distinctly a British product. The British pediatricians are greatest as clinicians; they keep us constantly at the bedside rather than in the laboratory, but in spite of this reversal of the present tendency, we recommend this book as a text-book on diseases of children, both to the practicing physician and to the student. It is a marvel of completeness and thoroughness; the style is clear and forcible; the arrangement is excellent and the matter is strictly up to date, containing, for example, references to Flexner and Lewis' latest work on poliomyelitis. One marvels how the author has been able to keep his mind wholly uninfluenced by the epoch-making work that has been done recently in Germany on the subject of infant-feeding, but this peculiarity is shared by all other English and most American writers. Throughout the book one is constantly impressed with its completeness and with the systematic arrangement of the subjects. Thus at the end of the book we find three chapters on the ear, the eye, and the skin in childhood. It would be a pleasure to speak in detail of the chapter on nervous and mental diseases, which covers nearly 200 pages, and of many other equally valuable portions, but space will not permit. The author does not believe in pictures—"the kindergarten method of teaching," as he calls it—and so none appears in the book. The binding and the typographic appearance are all that could be desired.

Diseases of the Heart and Aorta. By Arthur D. Hirschfelder, M.D., Associate in Medicine, Johns Hopkins University. With an Introductory Note by Lewellys F. Barker, M.D., Professor of Medicine, Johns Hopkins University. Cloth. Price, $6. Pp. 632, with 329 illustrations. Philadelphia: J. B. Lippincott Co. (1910).

This volume is destined to become a valuable reference work for the practitioner and a more familiar and necessary companion to the teacher of internal medicine. A cursory comparison of this book with Samson's "Diseases of the Heart and Aorta," written twenty years ago, is instructive. In the older treatise symptomatology received more attention, and, of the methods of examination, auscultation and percussion were strongly emphasized. The sphygmograph was expounded at great length and an importance attached to its arterial tracings that is no longer conceded. Turning from the old to the present volume we note the dominant influence of physiologic studies, including the results of experimental observation. The arterial tracings have been replaced by simultaneous tracings of heart, artery and vein by which alterations and irregularities of cardiac rhythm can be definitely analyzed. The arterial sphygmomanometer has developed a great field of knowledge. The *x*-ray has given a clear photograph of heart and aorta. The discovery of the bundles of His has revealed many of the secrets of arrhythmia. The electrocardiagram has made its debut and promises well. The author has written a discriminating chapter on drug treatment and has successfully condensed the methods and merits of gymnastics and hydrotherapy. A chapter on the effect of anesthetics on the heart and circulation and on the choice of anesthetics would be a desirable addition. The arrangement of the contents is sometimes difficult to follow and the inclusion of case reports is a doubtful asset. But on the whole the book represents one of the most solid contributions of recent years to medical literature.

A Manual of Nursing. By Margaret Frances Donahoe, Formerly Superintendent of Nurses and Principal of Training School, Philadelphia General Hospital. Cloth. Price, $2 net. Pp. 489, with 52 illustrations. New York: D. Appleton & Co., 1910.

This manual takes the nurse through the whole course of her hospital training and makes the application of the knowledge thus acquired to her private work. The author, being herself a nurse and for many years a superintendent of nurses, has overlooked little that should be incorporated in such a book. Anatomy is not considered but diseases and their symptoms are described simply, so that the nurse may have a sufficient understanding of their nature to assist physicians. Critical symptoms or turns in the patient's condition are described, and what to do in emergencies so that the nurse is forearmed as well as forewarned in regard to exigencies. The nurse's point of view is the one constantly kept in mind, and the book, therefore, has not the fault of some books on nursing written by physicians, which enter too deeply into matters that belong properly in the province of the physician and not in that of the nurse. The author's style is simple and concise, and easily understood by the beginner. The manual is a good one.

Praktische Kinderheilkunde in 36 Vorlesungen für Studierende und Aerzte. Von Dr. M. Kassowitz in Wien. Paper. Price, 18 marks. Pp. 653, with illustrations. Berlin: Julius Springer, 1910.

This book is in the form of a series of thirty-six lectures. Although not a complete treatise, it covers the more important subjects admirably with perhaps one exception, that of the gastro-intestinal diseases, which are all described in a single chapter. The book is of especial value since it represents the author's personal experiences with all of the conditions described, and one feels that it is his text-book, his point of view, his therapy, and not a mere compilation of the theories and practices of other authors.

The chapters on rickets are good. Kassowitz more than any other writer has been the advocate of phosphorus in the treatment of rickets, and goes into the subject, perhaps even to greater length than necessary. The four lectures devoted to rachitis and related conditions give one a good insight into the complex question of the relationship of rachitis and tetany, splenic anemia, etc. The chapter on congenital syphilis is also very instructive. Taken as a whole, the book is a valuable addition to pediatric literature.

The Care and Training of Children. By Le Grand Kerr, M.D., Author of "Diseases of Children," etc. Cloth. Price, 75 cents net. Pp. 233. New York: Funk & Wagnalls Co., 1910.

The book deals with children after the age of infancy on to adolescence. The author speaks not only as a physician, but also from the experience of a parent who has given the subject careful study and attention, so that matters pertaining to the physical welfare of the child are entered into, such as clothing, diet, bathing, sleep, the bowels and teeth, and the lighting, heating, ventilation of living-rooms, education, parental relations, government, punishment, moral training, amusements, literature, friends, etc., and the important questions of sex enlightenment and the matter of evil habits are discussed in a practical, common-sense way. The book should be helpful to parents in the training of children.

Diätetik innerer Erkrankungen zum praktischen Gebrauche für Aerzte und Studierende. Von Dr. Theodor Brugsch. Paper. Price, 4.80 marks. Pp. 245. Berlin: Julius Springer, 1911.

The author of this little work avoids theoretic discussions, and after a brief account of the physiology of nutrition enters at once on the description of the dietetic treatment of the various forms of disease. The pathology is briefly considered and the treatment is described in such a way as to give a clear statement of the general principles and at the same time sufficient detail for the practical guidance of physicians acquainted with German.

Medicolegal

Admissibility in Evidence of Physician's Account Books—Corroboration in Action Against Administrator

The Supreme Court of New Mexico affirms a judgment for the plaintiff in the case of Radcliffe vs. Chavez (110 Pac. R. 699), an action by a physician, against an administrator, on a claim for services. The court says that the testimony showed that the initial memorandum of professional visits was in two physicians' pocket day-books, which were received in evidence, but, while recording all the visits, they failed after a certain date to record the charges for such visits. However, two other books, called ledgers, might be classed as books of original entry and be considered admissible in evidence to the extent that the entries in them were original entries, if otherwise competent under the statute.

With reference to a statutory provision that the books of account of any merchant, physician, or other person doing a regular business and keeping daily entries thereof may be admitted in evidence as proof of such accounts on condition that he kept no clerk, or else the clerk is dead or inaccessible, on proof, by his customers, that he usually kept correct books, etc., the court holds that the fact that a physician's wife from time to time made entries in such books from his dictation did not constitute her a clerk so as to render the books inadmissible. The work "clerk," as used in the statute, implies more than a mere amanuensis. It means one having knowledge of the business so as to be able of his own knowledge to testify as to it. And as to proof by customers, it is sufficient if it be shown by them that during a period of years they have always found their accounts as tendered correct, coupled with testimony that such accounts were taken from the books in question; it not being essential that the customers shall have actually examined such books and compared their accounts with them. Where, therefore, as in this case, two patients come in and testify that their accounts as presented were uniformly correct, and where it is shown that such accounts were drawn from the books in question, the law infers from the treatment of the two a like treatment of the remainder, and considers the verity of the books established.

Then, books of account shown to conform to the requirements of the statute referred to are admissible in evidence, and, when so admitted in a suit against an administrator, may constitute "other material evidence" corroborating the claimant, as required by statute in an action against an administrator.

But the claimant went further in this case. His account was composed of several classes of items: (1) 167 visits for which $5 a visit was charged; (2) extra charges for some sixteen ordinary examinations of urine at $5 each; (3) five microscopic examinations necessitating trips to Albuquerque for which extra charges of $25 each were made; (4) washing out bladder six times at $10 each; (5) for limiting practice in order to stay near patient sixty-nine days at $5 per day; (6) for all-day and all-night service on the date of the patient's death $50. The plaintiff testified to the correctness of all of these charges, but, being of six separate classes, corroboration of all of one would not be sufficient to sustain the other.

Besides the claimant's books of accounts which, as has already been seen, were properly received in his behalf, and, when so received, were material evidence corroborating his testimony, the testimony of his wife showed that he had attended this patient as physician a number of times during the period charged for. Another physician testified to a knowledge of the case and to the necessity for examination of the urine, both ordinary and microscopic, to the fact that six of the former had been made with his help and to the reasonableness of the charges made therefor, to the presence of the claimant there night and day of the date of the last charge, to the fact that his presence was for the purpose of keeping the patient alive until some one who had been notified could arrive, and to the reasonableness of the charge of $50 therefor, to his knowledge of the fact that the claimant had for a considerable period previously to the death of this patient limited his practice to him, and declined outside practice, and that a charge of $5 a day was a reasonable charge for such limitation. He further testified that $2 was a reasonable price for the ordinary visit of a physician. A woman testified that she was nurse in attendance on the patient for two months and eleven days before his death, and that during that period, on the patient's request, the claimant attended, making sometimes two and sometimes three visits a day and sometimes at night, and that from about the beginning of such period the patient asked the claimant to be in attendance on him constantly during the time until he either died or got well. This last was corroborative of the claimant's testimony to the effect that he had on the special request of the patient limited his practice so as to be near him during the last sixty-nine days of his illness. The court deems this testimony, in connection with the books sufficient to corroborate and sustain all six of the classes of items above mentioned.

Testimony of a witness as to seeing the claimant's buggy stop at the patient's house was competent evidence as corroborative of the claim that he visited the patient professionally.

Practicing Medicine—Assignee of Claim of Unauthorized Practitioner

The Court of Civil Appeals of Texas affirms a judgment for the defendant in the case of Barnes vs. Sparks (131 S. W. R., 610), where he was sued on a note for $100 dated in January, 1905, and pleaded that the note was given for professional services rendered and to be rendered by one Dr. Dunnagan as a physician, and alleged that the latter was not at the time the note was given authorized to practice medicine in Hamilton county, where the note was executed, because he had not caused his license to practice medicine to be recorded in that county.

The defendant testified that he was afflicted with asthma and that Dr. Dunnagan came to his residence in Hamilton county, represented himself as a physician and agreed to cure him for $100; that he accepted the offer and executed to Dr. Dunnagan the note sued on; that immediately after the execution and delivery of the note Dr. Dunnagan gave him a dose of medicine, and that he thereafter received other medicine in pursuance of Dr. Dunnagan's contract, and did not know who sent it, unless it was Dr. Dunnagan. He also admitted that at the time he executed the note he signed a written contract with a medical institute, which was signed by the latter by said Dunnagan as diagnostician. Dr. Dunnagan testified that he did not prescribe for the defendant or give him any medicine; that he examined him, diagnosed his case; that he was prescribed for by a physician of the institute at Dallas, and that the medicine was furnished by that institute. The court thinks that the defendant's testimony warranted the conclusion that Dr. Dunnagan was practicing medicine on the occasion in question, and that at least part of the consideration of the note was for professional services rendered by him at that time.

Furthermore, the court overrules the contention that the laws of Texas do not make it unlawful for an assignee to maintain an action to recover for professional services of a physician prohibited by the statute from practicing. It holds that such defense is available against an assignee, unless such assignee is entitled to protection as an innocent purchaser and bona fide holder.

Refusal to Submit to Treatment Must be Unreasonable to Affect Verdict

The Supreme Court of Appeals of Virginia, in Roanoke Railway & Electric Co. vs. Sterrett (68 S. E. R., 998), a personal injury case brought by the latter party, holds correct an instruction which told the jury that if they believed from the evidence that the plaintiff unreasonably refused to submit to the treatment of physicians, or unreasonably refused to follow their instructions in regard to her injuries, and that in consequence of her refusal so to do her injury was aggravated and increased, then she could not recover damages to the extent that her conduct resulted in damage to her, and which might have been avoided and prevented by submitting to the treatment and following the directions of her physicians. The court says that objection was made to the interpolation of the word "unreasonably" in the instruction. The physicians alluded to were the surgeons of the defendant company employed by it to attend the plaintiff. She had also engaged physicians of her own selection, and by the instruction as originally offered was held bound at the risk of curtailing her recovery of damages to submit to the treatment prescribed by the defendant's surgeons whether reasonable or unreasonable. The amended instruction correctly told the jury that the plaintiff's right of recovery could be affected only by her unreasonably refusing to submit to the treatment or follow the instructions of physicians.

One Registration Only Required

The Court of Appeals of Georgia holds, in Jones vs. State (69 S. E. R. 315), that an indictment or accusation, charging a violation of section 1479 of the Political Code of Georgia of 1895, in that the defendant did practice medicine without registering in the office of the clerk of the superior court, is fatally defective, if it fails affirmatively to allege that the county in which he is charged with having practiced medicine without registering is the county wherein he resided. The law requires only one registration by a practitioner of medicine before he commences to practice medicine in Georgia, and that registration is required to be made in the office of the clerk of the superior court of the county wherein the practitioner resides.

6 An Improvement in Audiometers. F. A. Faught, Philadelphia.

1. **Proper Management of Neglected Children.**—The plan of work followed by the Speedwell Society of Morristown, N. J., is described by Chapin; the infants are boarded out under supervision of visiting nurses. He shows that if the plan could be carried out generally in the place of institutional work for feeble, neglected babies, a large majority of them would be saved. No capital is required to be tied up in a large building or plant. The plan has proved to be economically sound as well as practically efficient.

3. **Primary Sterility in Women.**—The observations and conclusions arrived at in Rongy's paper are based on an analysis of 120 patients who presented themselves for treatment for primary sterility during the past ten years. Only those cases are included in which both husband and wife were examined. In eight patients there was sterility in either a brother or a sister. Three of these patients presented a few symptoms that pointed to some congenital defect of the genital organs. The husbands of these patients had active and living spermatozoa. Nearly 85 per cent. of the women suffered from dysmenorrhea, particularly during the first two days, a fact which goes to prove that the pain was not merely due to mechanical obstruction, but that some derangement of the genital tract, most probably of inflammatory origin, was present, for were it only of mechanical origin the pain would have ceased as soon as the full flow was established.

Most of the patients attended to their housework. Two were teaching school, six had millinery shops, eight divided their time between house work and small stores they owned, two were stenographers, one a dentist. Prior to marriage the majority of the patients had been engaged in sedentary occupations in close quarters and for prolonged hours, were rather anemic, and not in a robust state of health. Fifteen were under 20 at the time of marriage, fifty-three between 20 and 25, thirty-eight between 25 and 30, seven between 30 and 35, four between 35 and 40 and one over 40. This is the proper ratio of the ages and therefore has no special significance. While some authors state that the marriages of near relations are more likely to be barren, in Rongy's experience this is *not* the case. Nine patients practiced masturbation daily from about the age of 16 until they married. Two continued the practice after marriage, stopping during the menstrual flow only. This continued practice resulted in complete sexual anesthesia in seven patients. In the presence of vaginismus sterility is the rule. Dyspareunia is usually a very prominent symptom in sterility. Thirty-two of the patients suffered from it.

In the 120 patients who came under Rongy's observation for the treatment of sterility he found that eighty-five, or 82 per cent. of the husbands admitted having been treated for gonorrhea for a period ranging from six weeks to two years. Eighteen had double epididymitis, with absolute sterility; twenty-one had single epididymitis, with absolute sterility in nine instances; nineteen gave a history of prostatitis and seminal vesiculitis; six of whom were operated on for stricture of the urethra, and three of whom suffered from azoospermia; the remaining twenty-seven evidently had anterior urethritis only, and in all spermatozoa were found. Three patients suffered from varicocele. In one patient the removal of this cured sterility of six year's standing. All the patients had azoospermia before the operation. Spermatozoa were found in all three cases three weeks after the operation. A small proportion of husbands suffer from azoospermia and oligospermia, which cannot be accounted for pathologically, and of necessity are classified as functional disturbances only. Closer inquiry brings out the fact that usually these patients have been excessively masturbating for a long period of time, with the result that the glandular structure of the testicles cannot supply the demand made upon them. Absolute impotence was found in three patients, two as the result of organic specific disease, one as the result of excessive masturbation. It is absolutely certain, says Rongy, that nearly 60 per cent. of women who suffer from primary sterility give evidence of gonorrheal infection. Next to the inflammatory processes the various displacements of the corpus and cervix uteri are the most important etiologic factors in primary sterility.

18. **Data on Bladder Tumors.**—In only twenty-eight of forty-one cases of tumors of the bladder collected from the records of the Massachusetts General Hospital by Davis were microscopic examinations of the specimens recorded. Twenty-five belonged to the epithelial group, two were sarcomata, one was a myoma—showing a great preponderance of epithelial tumors. Seventeen of the specimens of epithelial tumors which had been preserved were personally studied; six of these showed satisfactory evidence of epithelial infiltration of the bladder wall and were classed as carcinomata; eleven or nearly two-thirds, were regarded as papillomata. Thirty-seven patients were operated on; in nine the operation resulted fatally within a month, giving an operative mortality of 25 per cent. In none of the malignant cases was a radical operation, as it is now understood, attempted, but merely such palliative measures as curettage, cauterization and partial removal resorted to, with the result that death from the disease occurred in every case within six months.

Of the twenty-eight patients who survived the operation, twenty-six were traced. Fourteen, or just 50 per cent., died of the disease, one of these surviving for five years in spite of repeated recurrences before finally succumbing. Twelve patients, including those who died of other diseases, had no recurrence so far as could be learned. Nine are known to have survived the operation one year. Seven survived the operation two years. Five survived the operation eight years. Three of the latter died of other diseases, leaving two patients living and well at the time of the report, respectively eight and ten years after operation. Of the five patients who survived for eight years, in only three were there pathologic reports on the specimens removed; one was a myoma, two were papillomata. Of the eight cases of papillomata in which the specimens were personally studied by Davis, one patient died as the direct result of the operation, one died of intercurrent disease eighteen months later without evidence of recurrence, one died two months after secondary operation for recurrence, one five years later of recurrence. One patient reported perfect health one year after operation, but has not been heard from since. One patient cannot be traced; one patient is well eight years after operation. One patient operated on in 1892, and again in 1897 for recurrence, has remained well up to the present time, thirteen years since the second operation. Davis has operated on fifteen patients. Nine had papillomata. Three were cases of cancer of the nodular, infiltrating kind. There was no operative mortality in these fifteen cases. Transperitoneal cystotomy was done in five cases, and simple suprapubic cystotomy in ten.

19. **Transperitoneal and Suprapubic Approach to Tumors of the Bladder.**—Scudder finds that, practically speaking, all tumors of the bladder cause death of the patient sooner or later. The supposedly benign papilloma causes death by hemorrhage or pyelonephritis. All so-called benign tumors are potentially malignant. A papilloma which shows no sign of malignancy may become malignant. If the operative deaths and the rapid recurrences of bladder tumors are combined under the one head of operative failures, these failures have occurred in 29 per cent. of the so-called benign tumors and in 46 per cent. of the cases of carcinoma. Of the urethral operations for papilloma, only 28 per cent. of the patients remained cured more than one year. Of the partial resections, 37.5 per cent. of the patients remained well more than one year. Of fifty-three patients with papilloma operated on through the urethra or suprapubically, or by partial resection, nineteen had recurrence. The statistics of Nitze in 1901 and 1905 are not corroborated by detailed reports of the cases and Scudder regards them as unusually fortunate results. In view of the above facts pointing to the great malignancy of papilloma of the bladder, and because of the poor surgical results that hitherto have been obtained by operative treatment, Scudder believes that we should regard, from an operative standpoint, all papillomata of the bladder as potentially malignant, and that they should be treated as if they were malignant growths, whether there are evidences of malignancy *in any* individual case or not. Certain of the small, apparently benign papillomata may safely be removed by the suprapubic method, but should be removed even with this

approach by a good margin of excised, healthy tissue. The transperitoneal approach to the bladder will enable the surgeon to attack successfully cases of malignant tumor of the bladder which, without this approach, might be forced to a more dangerous extraperitoneal cystectomy.

20. **Intravesical Operations for Tumors of the Bladder.**—According to Binney, the published results of intravesical operations do not, at present, warrant the adoption of the method for the removal of primary growths, except in cases of very small tumors or in patients in whom a suprapubic cystotomy under an anesthetic is contra-indicated. In cases of repeated recurrences after suprapubic operations, the method is to be recommended over the performance of frequent suprapubic operations.

34 *Specific Cure of Yaws with Salvarsan. R. P. Strong, Manila.

30. **Tolerance for Alkalies in Asiatic Cholera.**—The most important findings reported by Sellards are the tolerance for alkalies and the change in the course of the disease. This tolerance, he says, may be dependent either on the cholera infection, or on the accompanying nephritis; apparently it is related more closely to the uremia than to the enteritis. The condition will be of more general interest if it proves to be present in uremia from other causes than if it is specific for cholera. Examination of the urine in cholera showed an almost constant increase in the excretion of ammonia. Cholera patients showed a definite tolerance of alkalies, a considerable excess of sodium bicarbonate being required to render the urine alkaline as compared with normal individuals. Within certain limits, the administration of alkalies not only failed to render the urine alkaline, but the acidity was even increased, as measured by titration. Following the injection of alkalies, there was sometimes a sudden and marked increase in the excretion of urea. The early administration of alkalies practically eliminated death from uremia.

The choice of alkali for treatment may vary somewhat in the different stages of cholera. The chief advantage of the normal carbonate would depend on its ability to absorb carbon dioxid, but apparently few deaths occur primarily from failure of the internal respiration. Sodium acetate may have some advantages, especially for the stage of collapse. As much as 80 grams within twenty-four hours have been injected, but perhaps this amount is slightly excessive in certain cases. As a general routine, sodium bicarbonate has been the most effective of the three salts. Its administration in collapse has several advantages and, in selected cases, concentrations of from 1 to 1.5 per cent. may be used. A weaker solution would probably be chosen which would be suitable for routine use in all cases of collapse. Early in the stage of reaction, as much as 60 gm. may be given within twenty-four hours. The most important indication for discontinuing its administration is the development of muscular cramps or twitchings. These symptoms may appear, although the urine remains acid, and may be considered as a reaction to the alkali. Several cases in which excessive amounts of alkali were tolerated without the appearance of this symptom terminated unfavorably.

There was a wide variation in the amount of alkali which resulted in the production of muscular contractions. The quantity apparently varied in direct proportion to the severity of the disease, although Loeb has shown that the precipitation of the calcium salts by a carbonate gives rise to muscular contractions. If administration of alkalies is delayed until uremic symptoms develop, secretion of urine follows promptly after injection of sodium bicarbonate, but the final termination is usually unaltered. The most important single factor in determining the amount and frequency with which alkali should be injected is the quantity of urine excreted. Sodium bicarbonate, in 1.5 per cent. solution, in 2 liter quantities, has been injected as soon as patients come out of collapse, and repeated at intervals of from twelve to twenty-four hours until a free secretion of urine follows. Aside from mild convulsions, the only other untoward symptoms following the injection of alkali was a temporary hematuria. This occurred in three of the fifty-five cases; it was slight in amount and persisted for from two to four days.

32. **Composition of the Blood in Asiatic Cholera.**—In the stage of collapse in cholera a loss of water in the blood was regularly encountered by Aron, accompanied by a corresponding loss of chlorids (salts). This water loss was constantly high in the blood of persons who died of cholera. In the later stages of the disease, the blood again shows an almost normal content of water, but the salts are not replaced to the normal amount. Therefore, the blood at this stage has a diminished salt content and is hypotonic.

34. **Specific Cure of Yaws.**—After using salvarsan in twenty-five cases of yaws, Strong believes it to be an ideal specific for this disease. Three or four days after the injection of the drug, the granulomatous lesions begin to disappear and in the course of from ten to twenty days they usually have disappeared entirely leaving a perfectly smooth, pigmented skin where the lesions previously existed. The absorption of tumor masses measuring several centimeters in diameter and about a centimeter in thickness in so short a time, and under the influence of no local treatment whatever, has been striking and surprising. Even in cases in which large granulomatous masses or deep ulcerations existed, these were healed within from two to four weeks. None of the patients has shown any signs of relapse, although each received but a single injection, and over four months have elapsed since most of them were inoculated.

40. **Drug Addiction in the United States.**—The thoughtful and foremost medical men have been and are cautioning against the free use of morphin and opium, particularly in recurring pain; and the amount they are using is decreasing yearly. Kebler claims that, notwithstanding this fact, and the fact that legislation, federal, state and territorial, adverse to the indiscriminate use and sale of opium and morphin, their derivatives and preparations, has been enacted during the past few decades, the amount of opium per capita imported and consumed in the United States has doubled during the last forty years. Not only has there been this increase in the use of opium, its preparations and derivatives, but large quantities of other habit-forming drugs have been used initially, introduced chiefly for medicinal purposes. For example, cocain (cocain hydrochlorid) has been employed for about twenty-five years, and the amount consumed at present per annum is estimated at approximately 150,000 ounces, an amount ten times as great as actually needed. In addition to this, it is well-known that large quantities of acetanilid,

under 20 at the time of marriage, fifty-three between 20 and 25, thirty-eight between 25 and 30, seven between 30 and 35, four between 35 and 40 and one over 40. This is the proper ratio of the ages and therefore has no special significance. While some authors state that the marriages of near relations are more likely to be barren, in Rongy's experience this is not the case. Nine patients practiced masturbation daily from about the age of 16 until they married. Two continued the practice after marriage, stopping during the menstrual flow only. This continued practice resulted in complete sexual anesthesia in seven patients. In the presence of vaginismus sterility is the rule. Dyspareunia is usually a very prominent symptom in sterility. Thirty-two of the patients suffered from it.

In the 120 patients who came under Rongy's observation for the treatment of sterility he found that eighty-five, or 82 per cent. of the husbands admitted having been treated for gonorrhea for a period ranging from six weeks to two years. Eighteen had double epididymitis, with absolute sterility; twenty-one had single epididymitis, with absolute sterility in nine instances; nineteen gave a history of prostatitis and seminal vesiculitis; six of whom were operated on for stricture of the urethra, and three of whom suffered from azoospermia; the remaining twenty-seven evidently had anterior urethritis only, and in all spermatozoa were found. Three patients suffered from varicocele. In one patient the removal of this cured sterility of six year's standing. All the patients had azoospermia before the operation. Spermatozoa were found in all three cases three weeks after the operation. A small proportion of husbands suffer from azoospermia and oligospermia, which cannot be accounted for pathologically, and of necessity are classified as functional disturbances only. Closer inquiry brings out the fact that usually these patients have been excessively masturbating for a long period of time, with the result that the glandular structure of the testicles cannot supply the demand made upon them. Absolute impotence was found in three patients, two as the result of organic specific disease, one as the result of excessive masturbation. It is absolutely certain, says Rongy, that nearly 60 per cent. of women who suffer from primary sterility give evidence of gonorrheal infection. Next to the inflammatory processes the various displacements of the corpus and cervix uteri are the most important etiologic factors in primary sterility.

18. **Data on Bladder Tumors.**—In only twenty-eight of forty-one cases of tumors of the bladder collected from the records of the Massachusetts General Hospital by Davis were microscopic examinations of the specimens recorded. Twenty-five belonged to the epithelial group, two were sarcomata, one was a myoma—showing a great preponderance of epithelial tumors. Seventeen of the specimens of epithelial tumors which had been preserved were personally studied; six of these showed satisfactory evidence of epithelial infiltration of the bladder wall and were classed as carcinomata; eleven or nearly two-thirds, were regarded as papillomata. Thirty-seven patients were operated on; in nine the operation resulted fatally within a month, giving an operative mortality of 25 per cent. In none of the malignant cases was a radical operation, as it is now understood, attempted, but merely such palliative measures as curettage, cauterization and partial removal resorted to, with the result that death from the disease occurred in every case within six months.

Of the twenty-eight patients who survived the operation, twenty-six were traced. Fourteen, or just 50 per cent., died of the disease, one of these surviving for five years in spite of repeated recurrences before finally succumbing. Twelve patients, including those who died of other diseases, had no recurrence so far as could be learned. Nine are known to have survived the *operation one* year. Seven survived the operation two years. Five survived the operation eight years. Three of the latter died of other diseases, leaving two patients living and well at the time of the report, respectively eight and ten years after operation. Of the five patients who survived for eight years, in only three were there pathologic reports on the specimens removed; one was a myoma, two were papillomata. Of the eight cases of papillomata in which the specimens were personally studied by Davis, one patient died as the direct result of the operation, one died of intercurrent disease eighteen months later without evidence of recurrence, one died two months after secondary operation for recurrence, one five years later of recurrence. One patient reported perfect health one year after operation, but has not been heard from since. One patient cannot be traced; one patient is well eight years after operation. One patient operated on in 1892, and again in 1897 for recurrence, has remained well up to the present time, thirteen years since the second operation. Davis has operated on fifteen patients. Nine had papillomata. Three were cases of cancer of the nodular, infiltrating kind. There was no operative mortality in these fifteen cases. Transperitoneal cystotomy was done in five cases, and simple suprapubic cystotomy *in ten.*

19. **Transperitoneal and Suprapubic Approach to Tumors of the Bladder.**—Scudder finds that, practically speaking, all tumors of the bladder cause death of the patient sooner or later. The supposedly benign papilloma causes death by hemorrhage or pyelonephritis. All so-called benign tumors are potentially malignant. A papilloma which shows no sign of malignancy may become malignant. If the operative deaths and the rapid recurrences of bladder tumors are combined under the one head of operative failures, these failures have occurred in 29 per cent. of the so-called benign tumors and in 46 per cent. of the cases of carcinoma. Of the urethral *operations for* papilloma, only 28 per cent. of the patients remained cured more than one year. Of the partial resections, 37.5 per cent. of the patients remained well more than one year. Of fifty-three patients with papilloma operated on through the urethra or suprapubically, or by partial resection, nineteen had recurrence. The statistics of Nitze in 1901 and 1905 are not corroborated by detailed reports of the cases and Scudder regards them as unusually fortunate results. In view of the above facts pointing to the great malignancy of papilloma of the bladder, and because of the poor surgical results that hitherto have been obtained by operative treatment, Scudder believes that we should regard, from an operative standpoint, all papillomata of the bladder as potentially malignant, and that they should be treated as if they were malignant growths, whether there are evidences of malignancy in any individual case or not. Certain of the small, apparently benign papillomata may safely be removed by the suprapubic method, but should be removed even with this

approach by a good margin of excised, healthy tissue. The transperitoneal approach to the bladder will enable the surgeon to attack successfully cases of malignant tumor of the bladder which, without this approach, might be forced to a more dangerous extraperitoneal cystectomy.

20. **Intravesical Operations for Tumors of the Bladder.**—According to Binney, the published results of intravesical operations do not, at present, warrant the adoption of the method for the removal of primary growths, except in cases of very small tumors or in patients in whom a suprapubic cystotomy under an anesthetic is contra-indicated. In cases of repeated recurrences after suprapubic operations, the method is to be recommended over the performance of frequent suprapubic operations.

40. ***Drug Addiction in the United States.***—The thoughtful and foremost medical men have been and are cautioning against the free use of morphin and opium, particularly in recurring pain; and the amount they are using is decreasing yearly. Kebler claims that, notwithstanding this fact, and the fact that legislation, federal, state and territorial, adverse to the indiscriminate use and sale of opium and morphin, their derivatives and preparations, has been enacted during the past few decades, the amount of opium per capita imported and consumed in the United States has doubled during the last forty years. Not only has there been this increase in the use of opium, its preparations and derivatives, but large quantities of other habit-forming drugs have been used initially, introduced chiefly for medicinal purposes. For example, cocain (cocain hydrochlorid) has been employed for about twenty-five years, and the amount consumed at present per annum is estimated at approximately 150,000 ounces, an amount ten times as great as actually needed. In addition to this, it is well-known that large quantities of acetanilid,

antipyrin, acetphenetidin and diacetyl-morphin, and smaller quantities of hydrated chloral, codein, para-amino-benzol-diethyl-amino-ethanol, etc., are used. The amount of opium imported per annum during the past twenty years is slightly less than 500,000 pounds. The average yearly decrease during the past ten years is about 20,000 pounds. The present deterring factors are antinarcotic legislation and publicity.

From a comparison of the amount imported here with that in countries having efficient restrictive legislation, like Austria-Hungary, Germany, Holland, Italy and Spain, Kebler says it is clearly evident that from 80 to 90 per cent. of the opium imported is used improperly. It is variously estimated by those who are conversant with the situation that the number of drug habitués in the United States varies from 1,000,000 to 4,000,000. Most of the states have enacted laws forbidding the indiscriminate sale of cocain and cocain-bearing products, and to a certain extent this also holds true for morphin and preparations containing it. Still, in many instances, there are some features which do not render such laws as effective as they might be. Many states are enforcing local laws regulating the sale of morphin, cocain, etc., within their jurisdiction, but they are unable to control the introduction of these habit-forming drugs from localities outside of the state, and for this reason the officials find it difficult to make material headway. Manufacturers, importers and wholesalers, until recent years, have been supplying these agents to all comers, but recent activity shows that they are anxious to see the illegal use of such habit-forming drugs suppressed, notwithstanding the financial loss which they may encounter. It is a well-known fact that many wholesalers refuse to sell undue amounts of cocain to retailers, and from this it can readily be seen that there is a decided movement on foot toward suppressing drug addiction, not only on the part of the public, but also of manufacturers and dealers in these commodities.

It is well known that there are many factors at work tending to drug enslavement, among them being the host of soothing syrups, medicated soft [illegible] in, asthma remedies, catarrh remedies, [illegible] cough and cold remedies, and the more notorious drug addiction cures. It is often stated that medical men are frequently the chief factors in causing drug addiction. In order to obtain information on this subject, letters were addressed by Kebler to practicing physicians, sanitariums treating drug addiction under direct supervision, and sanitariums treating it both under direct supervision and in absentia only, throughout the United States. The data thus secured, with observations, are most interesting, but being published in tabular form cannot be abstracted.

58. **Intestinal Resection.**—When making an intestinal resection, Wallace found that a lateral anastomosis with a Murphy button by a certain method may be done with such rapidity that an immediate resection may safely be accomplished. He uses the Hartley method in making the lateral anastomosis, dropping half of a Murphy button into each end of the gut which is left after resection, and, after closing the ends of the gut by the Lilienthal method, pushes the halves of the button together. Lilienthal simply ties off the gut with twine instead of turning in or sewing up the end. Wallace has now used it six times with six successes. In three cases of strangulated hernia, he resected, made a lateral anastomosis with the Murphy button by the Hartley method, tied off the ends of the gut with fine linen or silk by the Lilienthal method, cut off the ends of the silk short and dropped the gut back, closing the abdomen without a drain. In another case of strangulated hernia he did the same, except that on account of the evident infection, he left a rubber drain down to the closed peritoneum. In one case of tuberculous salpingitis in which resection of the gut was necessary, it was accomplished in this way without drainage. In one case of appendicitis, in a child of 8, the end of the cecum, 1½ inches above the root of the appendix, together with the appendix and its mesentery, were tied off with one ligature and cut away.

59. **Abdominal Injuries.**—Goodrich urges an immediate aseptic abdominal section in every doubtful case of abdominal injury. Some of the important points in the surgical treatment of abdominal injuries are explained by him as follows:

1. Apply active measures to overcome or lessen shock, unless signs of active hemorrhage make quick action imperative. A reasonable time (one-half to three hours) may be allowed in cases of profound shock, to promote a helpful reaction.

2. Cleanse the skin as thoroughly and as widely as in any other abdominal case, notwithstanding the presence of indication for rapid work.

3. Precede an exploration by an intravenous saline infusion or a transfusion of blood when symptoms of hemorrhage are marked. As Crile has noted, "We may in this way transform a hopeless case into an average risk."

4. Make the search for intra-abdominal injuries thorough and systematic.

5. Cleanse the peritoneum thoroughly of septic material and blood, or fluid of any kind. This is best done by large gauze sponges, followed by copious irrigation, leaving the abdomen partly filled with saline solution.

6. Secure absolute hemostasis and water-tight repair of all wounds and ruptures.

7. Introduce drains whenever viscera have been penetrated or ruptured.

8. Use intravenous infusions of normal saline solution freely postoperatively in cases of marked shock or acute anemia.

9. Adopt the Fowler position and the ice coil in all cases as soon as reaction from shock is obtained.

10. If intestinal paresis supervenes, lavage every four hours will accomplish more than enemata.

Goodrich records a recent recovery from intestinal paresis so extreme as to be accompanied by frequent fecal vomiting, by the use of this measure.

74. Persistence of Strychnin in a Corpse.—On Nov. 15, 1909, a man of 53 died under suspicious circumstances. The body was buried on Nov. 19, 1909; on November 29 of the same year it was disinterred, and certain organs removed and sent to the late Franklin G. Robinson for analysis. Professor Robinson's notes record that he found strychnin, but, owing to illness, he was unable to appear personally at the trial. The body, therefore, was exhumed a second time on March 18, 1910, the other organs removed which were sent to Cram. The body had been frozen most of the time, but the grave when opened was full of water, which was allowed to drain off. An embalming fluid of acid reaction had been used when the body was first buried, which made it appear likely that any strychnin would be dissolved out. The method used for determining strychnin was the usual one of extracting with alcohol made acid with acetic acid, evaporating the extract to soft dryness, extracting the residue with water, extracting the acid water solution with chloroform, and then the same solution made alkaline with chloroform, the strychnin coming out in the last chloroform extract. The strychnin was then purified by absolute alcohol. From 454 grams of the lung, 133 grams of kidney, 446 grams of muscle, 850 grams of small intestine and 560 grams of brain, each being tested separately, no strychnin was obtained. From 803 grams of liver was obtained 0.0015 gram of strychnin, and from the spinal cord 0.0033 gram. The spinal cord itself weighed 25 grams. The note-books of Professor Robinson record that in 290 grams of stomach contents he found 0.0277 gram of strychnin, and in 45 grams of kidney 0.0003 gram of strychnin. The spinal cord, being better protected from the action of the water in the grave, which was acid from the embalming fluid, had retained the strychnin better than the other parts.

85 *Congenital Stenosis of Pylorus. A. D. Bevan, Chicago.
86 *Cerebrospinal Meningitis, Its Etiology, Diagnosis, Prognosis and Treatment. C. H. Dunn, Boston.
87 *Relation Between Carpal Ossification and Physical and Mental Development. E. Long and E. W. Caldwell, New York.
88 *Frequency and Significance of Albumin in the Urines of Normal Children. S. McC. Hamill, Philadelphia, and K. D. Blackfan, Cambridge, N. Y.

85. Congenital Stenosis of the Pylorus.—Bevan's conclusions are that congenital pyloric obstruction is a definite, well-established pathologic condition; that it produces, for him who has seen it, an easily recognized clinical picture; that it can, as a rule, be differentiated from other conditions simulating it; that if early recognized it can be permanently relieved by overcoming the obstruction by modern surgical methods; and that the individual so saved can grow up and develop in a perfectly normal way.

86. Cerebrospinal Meningitis.—The specific methods of treatment which in Dunn's opinion are available in the various forms of cerebrospinal meningitis, and which should be more widely tried, until further evidence proves or disproves their value, are: tuberculous—early and repeated lumbar puncture; epidemic—antimeningitis serum; pneumococcus—antipneumococcus serum; streptococcus—antistreptococcus serum; influenza—early and repeated lumbar puncture; staphylococcus—homologous vaccine.

87. Carpal Ossification and Physical and Mental Development.—The investigations described by Long and Caldwell were made with a view to applying the ingenious method proposed by Rotch, that the stage of ossification of the carpal bones as determined by the radiograph may be used to standardize or grade growing children as to their capacity for physical and mental work. As a result of their investigation, Long and Caldwell are led to believe that the ossification of the one wrist of an individual is not the exact index of the ossification of the other wrist, and therefore it seems probable that the same inexact relation exists between the wrist and the remainder of the skeleton. Age, height and weight increase in general with advance in carpal ossification, but with many exceptions among both sexes. It would be impractical at least to regulate the mode of life of these children according to this classification alone, e. g., Class B includes a very bright child, 2 years, 6 months and 15 days old, and a very dull child of 6 years, 7 months and 29 days: Class D includes a child of fair intelligence, 2 years, 2 months and 2 days old, with a very bright child of 7 years and 29 days. They can find no relation between the degree of carpal development and quality of mind. Some idiots are as far advanced in carpal ossification as some normal children of good mentality and similar chronologic age. The relation between the stages of puberty and those of carpal ossification is too indefinite to warrant the latter's use as an index of physiologic development. And, finally, though carpal development alone is not an exact index, still when observed at intervals, and considered with other factors, it may become an aid in estimating the rapidity of growth of the skeleton in children. They believe that closer attention should be paid by the medical profession to the regulation of physical and mental tasks more in accordance with the individual child's capacity, and that development of the ossification centers of the skeleton may become a factor, toward this result.

88. Albumin in the Urine of Normal Children.—In each specimen of urine, Hamill and Blackfan determined the color, the appearance, the specific gravity, the reaction (in twenty-four-hour specimens, the total acidity), the presence or absence of albumin, sugar, acetone, diacetic acid, indican, urobiligen and phenol; and microscopically, the presence or absence of cells, casts, cylindroids and crystals. Four hundred and forty-five specimens of urine were examined. These were obtained from 124 children, ranging in age from 18 months to 14 years. During the period of examination the usual routine of life was followed, except that the children were kept from school. There was no relationship between the specific gravity and the form or amount of albumin. The reaction had no influence on the production of albumin. Sugar, acetone and diacetic acid were never found. They may, therefore, be considered as having no bearing on the production of albumin. Indican, phenol and urobilinogen, when present, were usually associated with albumin, but albumin was sometimes absent when they were all present, and the amount was never greater when associated with them than it was in the cases in which they were absent. Crystals, when present in amounts, such as are occasionally found in normal children, are in no way responsible for the associated albumin. The mild disturbances of the intestinal digestion, as shown by the examination of the stools, were not sufficient to account for the occurrence of albumin. The blood-pressure was within the normal range in all cases and, therefore, did not influence the albumin output. The albumin elimination was the same on mixed and exclusive milk diets. They found no children in whom the albumin excretion corresponded to the requirements for postural or orthostatic albuminuria, a rather surprising result in view of the frequency with which this condition is supposed to occur.

Thirty-two and one-half per cent. of the children showed occasional, hyaline casts and cylindroids in the urine. The authors do not consider their "occasional presence" as indicative of a lesion of the kidneys, but rather as suggesting a temporary overtaxation of the kidneys resulting from variations in the habits of life of the individuals, which are too slight to be recognized. Eighty-eight and seven-tenths per cent. of the urine of these 124 children showed albumin, 27.4 per cent. showed serum-albumin alone and in combination; and 85.4 per cent., an albuminous body precipitated by acetic acid in the cold. These two albumins were nearly always present in very slight traces, occasionally in slight traces and rarely in traces. In thirty-eight children the twenty-four-hour specimens showed nucleo-albumin in all but one, and in this case samples examined over prolonged periods of time showed nucleo-albumin frequently. In these thirty-eight children, the percentage of serum-albumin was very much larger (42.1 per cent.) than in the total number of cases examined. The authors believe, therefore, that it is possible to demonstrate in the urine of every presumably healthy child traces of an albuminous body precipitated by acetic acid. Consequently, this substance must be regarded as an exceedingly common, if not constant manifestation in the urine of children under 14 years of age, and as of no clinical significance. Hamill and Blackfan do not believe that serum-albumin in the amounts in which it appears in these children indicates a diseased condition of the kidneys any more than does the presence of occasional hyaline casts and cylindroids, and that its etiology may be considered the same as that given for these former elements.

99. **Manifestations of Defective Feet.**—Watkins emphasizes the importance of always being on the outlook for what is called "pronated foot," a condition which is capable, without presenting subjective local manifestations, of giving rise to remote symptoms mistakable for those of lesions so dissimilar as sciatica, coccygodynia, uterine relaxation and allied disorders, a variety of backaches and spinal osteo-arthritis. The treatment of those defects for which pronated foot may be mistaken is either operative or mechanical. The explanations of the various subjective symptoms of pronated foot are found in the disturbances it inaugurates in the normal mechanics of the erect attitude. Watkins reports several cases in point and discusses the mechanism of walking from the anatomic viewpoint.

100. **Etiology and Treatment of Enuresis.**—With the object of determining the value of thyroid treatment of enuresis, Fleischner treated ten patients as follows: One-fourth grain thyroid extract was given three times a day, increasing to ½ grain three times a day. Fluids were not allowed after 4 p. m., and the foot of the bed was decidedly elevated at night. Of these ten patients, eight improved; two did not improve. Of the eight who improved, in four cases circumcision had been previously performed without result. Fleischner believes that the postural and dietetic treatment are of undoubted value; their action is, naturally, combined. Mothers are advised to give the children no fluid beyond a glass of milk for the evening meal, after 4 in the afternoon; then they are told to place blocks under the foot of the bed so that that part is raised about 8 inches. The object of this is to keep the urine from coming down and irritating the neck of the bladder, and it is often efficacious.

115. **Stenosis of Lower End of Esophagus.**—Three cases are reported by Akin. He emphasizes several points, first of which is the importance of having the proper kind of bougie. The only reliable instrument, in his opinion, is a long 24 or 25-inch whalebone bougie, stiff enough so that it will not bend, but will go straight through where it is directed. His second point is the use of the silk thread swallowed the day before so as to allow it to become firmly engaged in the bowel below the stomach. This is a simple but highly commendable procedure, he asserts, because it enables the operator to introduce the bougie or dilator directly to the permeable point of the stricture and to use such force as is required to pass on into the stomach with a certain knowledge that his instrument is not going to deviate to the right or left and perhaps make false passage into the lung or pleural cavity. Akin favors dilatation of the stricture whenever this is possible.

126. **Alterations of the Circulation in Goiter.**—Guthrie and Ryan record additional observations on the results following alterations of the circulation in goitrous thyroids, and further discuss these results in the light of other observations and considerations with a view of determining the factors concerned in their production. They found that marked anatomic changes occur in enlarged or goitrous thyroids of dogs after alteration of the circulation. The greatest changes observed occur when the circulation is reversed in the inferior thyroid vein by anastomosing this vein with the central end of the common carotid artery, or by making the anastomosis of the artery with the peripheral end of the internal jugular vein

below the point of origin of the inferior thyroid vein. The gross changes consist of a temporary swelling, followed by a marked decrease in size of the lobe on the operated side. The lobe feels much harder and denser. Microscopically, if the goiter be of the hyperplastic type, generally more normal staining colloid is seen after the operation; while if the goiter be of the colloid type, a decrease in the colloid substance is observed. In both cases the operated lobes in size, physical properties and histologic structure tend to revert to the normal. The authors believe that the change may rationally be interpreted from the standpoint of primary interference with the respiration of the tissues, which results in the death, disintegration and disappearance of abnormal tissue constituents. Also, accompanying the secondary effects due to the reactions of the tissues, absorption is probably increased so that the abnormal substances are quickly moved from the gland which accounts for their rapid disappearance. The more nearly normal tissue elements being more resistant or perhaps more favorably situated to revive, under the more nearly normal circulatory conditions established through the reaction of the tissues to the adverse condition, which indeed is strikingly similar to the current conceptions of an inflammatory reaction, resume and retain a more nearly normal function.

The reaction set up in the tissues is explainable as being due to the edema. But this may be only the indirect cause, for the accumulation of metabolic products together with substances originating from the death of tissue elements would probably act either together or the latter alone, more directly in producing an inflammatory reaction. On the whole, the results indicate that general symptoms of goiter are at least in part associated with deranged functions of the thyroid apparatus.

148. **Peculiar Red Blood-Corpuscles in Severe Anemia.**—This patient has been under observation, at intervals, since 1907. She is a negress, aged 25, a native of southwestern Virginia and has lived there all her life. When first seen, Oct. 25, 1910, she complained of weakness, soreness and pain in the left side, and a sore on the left leg. She has never had good health. When a child she had measles. Menstruation began when she was eighteen and has been fairly regular, normal in amount, and with little pain. When a small girl, she had pneumonia, with pleurisy on the left side, and claims to have had pain in that side since that time. Three times within the last five years she has had chills and fever, supposedly malaria. She has never had rheumatism. There is no history of a chronic cough, but she is often troubled with epistaxis and sometimes spits up bloody mucus. She has shortness of breath on exertion, night sweats, and sleep starts, and is also troubled with swelling about the wrists and ankles. After eating, she occasionally has severe abdominal pain and is often troubled with indigestion and constipation. There is no history of any kidney or bladder trouble, gonorrhea or syphilis. The woman is a cook and has always done house work. In September, 1910, she weighed 155 pounds, but has fallen off since that time.

About five years ago she first noticed that she became dizzy and short of breath on slight exertion; and was also troubled with swelling in the feet and ankles. About the same time, she knocked the skin off of the left shin and the wound became infected, causing a bad ulcer. Some time after this an ulcer started on the right leg, though she does not remember having hurt it. She was also troubled with severe pains in the abdomen. These pains would start on the left side and radiate to the region of the liver, and were sharp and stabbing in character. She returned to her home in December of the same year feeling much improved. In March, 1908, she was operated on for gall-stones, 107 being removed. She continued to have good health until the following April; at which time she complained of severe pain in her left side. This pain was more or less constant, worse in the day than at night, and also increasing on taking a deep breath and on pressure. She also complained of being constipated—the pain being worse then than when the bowels moved regularly. Physical examination showed the mucous membranes to be pale; tongue coated; lungs and liver negative. The heart was slightly enlarged, with a systolic murmur heard best at the apex and transmitted to the axilla. The average temperature ranged from 99 to 100 F., pulse from 80 to 100, blood pressure was 105. Blood examination, April, 1909, showed: red cells, 2,000,000; white cells, 11,000; hemoglobin (Sahli), 50 per cent. Differential white count was as follows: polymorphonuclears, 63 per cent.; small mononuclears, 25 per cent.; eosinophils, 4 per cent.; mast cells, 6 per cent. The red cells showed poikilocytes in a variety of shapes, the most common variety being of a crescent shape. At several subsequent examinations cells of the same shape were found.

1. **Organization in the Profession.**—Osler points out that there is an organization in the profession and an organization of the profession—the one deals with the mutual relations of medical men with each other and with the public, the other is concerned with his relations to the state, and with the faculty of medicine in its corporative capacity. There are numerous organizations, but the profession is not yet self-controlled through any one representative body, as it certainly should be in this democratic age. Than medical practitioners, says Osler, no men need more acutely the benefits of cooperation, and yet they are notoriously difficult units to unite. Once split off from the parent college or school, a majority of practitioners live lives of isolation, often, indeed, of great loneliness. Even in a city a very busy man may see surprisingly little of his colleagues and, what is worse, he may desire to see still less. Of the value to the local practitioner of a medical society and of a library all are agreed. The medical society may do three things. It is the most important single factor in the promotion of that unity and good fellowship which adds so much to the dignity of the profession. The second great function is postgraduate instruction; to each member the medical society should be a sort of clearing-house of his clinical experience. A third equally important function is the support of a library. A few good journals and the new books are all that the members should ask of the library committee. Osler then deals more particularly with the function of the county hospital in postgraduate education. As a class, he says, physicians do not appreciate enough the importance of continuous education in their professional life. To be up to date a man must keep in touch with the advance guard of the profession, and this is not easy to do in any course of reading, however thorough; he must come in contact with the men who are doing the work. While it is not too much to ask that a man should break away every few years from the routine of practice and go to a postgraduate school, there is another and easier way—the postgraduate school may be brought to him. Here comes in a function of the first importance in a county hospital, one can do his own postgraduate work.

3. **Radium in Gout and Rheumatism.**—Of 100 patients with chronic rheumatism treated by His with radium, forty-seven were improved, twenty-nine were considerably improved, five nearly cured, thirteen were uninfluenced by the treatment, and the result was not apparent in six. There were several cases of myalgia. A few of these patients have reacted in a most marked manner to the radium treatment, others were improved, and others, again, were absolutely uninfluenced. On the whole, His found that the younger the individual, the less advanced the illness, the better the results. Even in very long standing cases alleviation of pain may, at all events, be looked for. The results in gout were more striking. He was able to observe and treat twenty-eight patients for a considerable period. Of these four remained unaffected, while in twenty-four great improvement in the condition was achieved. Some of the patients have remained free from symptoms for a year after the termination of treatment. His was in a position to examine the blood for uric acid, both before and after the treatment, in eighteen cases. In fifteen the desired result was effected promptly; in a severe case of gout the blood was found to be free from uric acid after fourteen days' treatment by drinking water containing radium. He observed tophi in the ear disappear on two occasions during the treatment. The clinical improvement, however, did not always run parallel to the uric acid content of the blood. His noted marked improvement in a patient who was energetically treated, in spite of the fact that the blood retained its uric acid. In another patient, who had gouty nodules all over the body, no uric acid was present in the blood either at the beginning or toward the end of the treatment, and yet the patient had one attack after another during the entire time. In the majority of cases, at all events, His concludes that in the treatment of gout radium is a very powerful remedy, even if some persons are refractory to the treatment.

4. **Right-Sided Pleural Effusion.**—As a result of the consideration of his cases, Geddes is confirmed in his opinion that one cause of sudden death in cases of right-sided pleural effusion may well be occlusion of the great veins as they approach the heart, and more especially occlusion of the inferior vena cava.

5. **Treatment of Nevi by Freezing.**—Bunch has successfully treated with carbon dioxid 300 nevi of various extent and size. Most of these lesions were sources of disfigurement, many of them being on the face; but some were in positions where only a sentimental feeling on the part of the parents, and no cosmetic necessity, seemed to make their removal desirable. Such were nevi of the vulva, of the penis, and of the margin of the anus, and they were interesting from the point of view of the possibility of sepsis; but Bunch has not seen one in these positions which gave any trouble or failed to react in the ordinary way or to heal up normally. Most of these patients were treated at the hospital and included capillary, stellate, cavernous and pigmented nevi; some were small and some were several inches in diameter, flat, or markedly raised above the adjacent healthy skin, forming prominent red or purple swellings. For all such cases, Bunch says, treatment by solid carbon dioxid cannot be improved on, but for large port-wine stains, involving part or whole of one side of the face, where a considerable area has to be treated at a single application, he prefers to employ liquid air.

6. **Gastric Cancer in a Youth.**—One of the chief points in this case is that it illustrates how misleading the abnormal age incidence of a disease may be in coming to a correct diagnosis. The temporary improvement, with proper medical care and nursing in the earlier stages of the case, is remarkable.

12. **"X" Bodies in Human Blood.**—These bodies were found in blood-slides made from a patient who was suffering from urticaria nocturna. The disease was of four months' standing. The patient was a white woman, aged about 18, married, and nursing a child 1 year old; the child was healthy. Every evening about 7 o'clock flat, solid, more or less elevated wheals, irregular in size and shape, began to appear all over the body. These wheals disappeared and others appeared till the early morning, when the eruption began to diminish, and about sunrise nothing was left and the patient looked normal, like any other person. The eruption was accompanied by a severe itching and burning sensation; there was no fever and no disturbance of any of the systems of the body. In one of the films, Balfour found typical "X" bodies in considerable numbers, free, and occasionally lying on the red cells. A fairly common form was a small body about one-eighth the size of a red corpuscle, spherical in form, and consisting of a faint capsule with a circular center staining deep blue. The majority, however, had centers more of a pale lilac than a blue color, and contained faintly staining material between their capsules and their centers. What may be called large and intermediate forms of a similar form were present, but in the former the capsule was not so defined, the appearance being rather that of a halo of more faintly staining substance surrounding a deeply stained spherical core. Very few forms with concentric rings were observed; and only one or two of large "solid" coccus-like type. Bodies described as fragmented were encountered. Some of these had only a chip, as it were, broken from them, or looked like biscuits from which one had bitten out a piece. Distinctly oval forms were seen, usually of considerable size, and also a curious oblong appearance. Small forms measuring 3 μ in diameter were met with, one of which showed a segmentation of the central spot into four; another no dark center, but dark spots at its periphery; and yet another a kind of inner capsule. Many of the smaller forms were homogeneous, showing no dark centers whatever, while some of the larger forms, with distinct cores, showed granular material between their

capsules and their centers. In this there were sometimes small blue spots or granules. Others, again, were irregular in shape, being what may be called "knobbed" bodies. Balfour found no trace of chromatin in these bodies; but lying free, there was a considerable amount of amphorous-looking material which took on a pale lilac stain like some of the smaller bodies. This was more plentiful in that part of the film where the bodies occurred. It will be seen, then, that the bodies are pleomorphic, although quite distinct from all the blood elements, and readily recognizable as specific entities.

15. **Magnesium Sulphate in Erysipelas.**—Four cases are reported by Choksy in which the immediate effects of the application of magnesium sulphate solution were extremely beneficial. Pain and swelling abated, fever decreased, and extension of the disease was controlled in the majority of cases. *A saturated solution of magnesium sulphate in water* (preferably strained through muslin) was applied round the limb or on the face as a mask, extending well beyond the inflamed area, in from 10 to 15 layers of gauze or a thin layer of absorbent cotton or lint, and covered with oiled-silk or wax paper. The dressing should be wetted as frequently as *it gets dry, about once in two hours. It should be removed* once in twelve hours for inspection and immediately reapplied. The affected area should not be washed during treatment.

22 *Treatment of Acute Pneumonia by Continuous and Persistent Diaphoresis. G. M. Reid.

20. **Autoplastic Ovarian Transplantation.**—Nattrass is convinced that it is possible to remove the ovary from its normal position in the female body and to transplant it on to other tissues. In the experiments performed by him, ovaries were successfully grafted on to the kidney, spleen, subcutaneously on the external oblique muscle, on the peritoneum, periosteum and the external intercostal muscles. When the transplanted ovary is examined in the early stage, it is found to be firm in consistence, whiter and slightly larger than normal. This is shown by the microscope to be due to swelling of the cells of the stroma, which have undergone fatty degeneration. This degenerative change was found to be present in most of the specimens examined. The amount seems to be inversely proportional to the vascularity of the tissues receiving the graft, and directly proportional to the thickness and density of the graft itself. Thus there was more degeneration in a subcutaneous, than in a renal or splenic graft. In the older grafts there is a diminution in the size of the ovary. There is an increase in the amount of the fibrous tissue, a progressive absorption and repair of pathologic products, a continued development of egg cells, and production and maturation of Graafian follicles, although not nearly to the same extent as in the normal ovary. The grafts become firmly adherent to the adjacent tissues by dense fibrous bands. The graft when placed in its new position is undoubtedly nourished by transudation of fluid from the lymph spaces of the adjacent tissue, hence the periphery of the ovary, or the egg-bearing part, always retains its vitality; but later, blood-vessels become developed and vascular union is established, the graft thus receiving blood from the arterial system. A female dog whose ovaries were removed from the abdominal cavity and were grafted, one on the external oblique muscle, and the other in the sheath of the rectus muscle, repeatedly showed all the symptoms of sexual heat, i. e., vulvovaginal congestion, and sanguineous discharge, and was warded by the dog, showing that the ovaries, even though in this abnormal position, continued to carry on their functions as organs of internal secretion and to regulate the sexual life of the animal. Nattrass believes that the autoplastic grafting of ovaries is a measure that ought to take its place and fulfil a definite purpose in conservative gynecologic surgery.

21. Also published in the *Australasian Medical Gazette*, December, 1910.

22. **Treatment of Acute Pneumonia.**—Reid claims that if free and persistent diaphoresis, which necessarily entails a primary dilatation of the skin capillaries, can be established in the first or congestive stage of a threatening pneumonia, the attack can be aborted. When the second or exudative stage has begun, and is progressing, the same method of treatment will by its action still prove effective in limiting the exudative process, and may, furthermore, have a vitally beneficial action in preventing the fatal accumulation of carbonic acid, and other morbid products engendered by the diminished lung function, *and increased metabolism by removing the same from the* system in or with the sweat. *Pari passu*, diaphoresis reduces body temperature, and checks tissue waste, etc. In effecting his object, Reid has trusted mainly to medicinal agents, with, in children, the additional aid of the hot mustard bath, and in adults the hot-pack or warm sponging. The drug which he *mostly employs is a physiologically pure salicylate* of soda, in four-hour doses, up to 15 or 20 grains, according to age, and. guided and controlled by the patient's temperature, taken and recorded every four hours. He has also used acetphenetidin in doses up to 10 grains every four hours with the same precautions. With both drugs he has been in the habit of *combining general and cardiac tonics and stimulants.* His results, in a limited number of cases, have been good, and he has specially noted the absence of cerebral symptoms where the diaphoresis was satisfactory. Several cases in which sweating was interrupted, or could not be properly established for obvious reasons, terminated fatally.

31 *The Antitryptic Index for Serodiagnosis of Gastro-Intestinal Cancer. J. C. Roux and R. Savignac.

31. **The Antitryptic Index for Serodiagnosis of Cancer.**—Roux and Savignac have simplified the antitrypsin test devised by Müller and Jochmann and modified by Fuld and Gross. They found the test positive in 89 per cent. of fifty-three cases of certain cancer and in 80 per cent. of the suspects. Except possibly in exophthalmic goiter, tuberculosis and early in pregnancy, the test was negative in the controls, and the conflicting findings possible in the conditions named would seldom, they think, lead to any confusion in diagnosis of cancer. They are convinced that negative findings may be regarded as almost certainly excluding malignant disease. Their technic requires only an hour to complete the test. They use a mixture of equal parts of milk and 2 per cent. solution of agar, filtered while still hot. The whole is then heated to 100 C. in the water bath, then cooled to 60 C. and poured out in a thin layer on Petri dishes. One drop of blood-serum is mixed with 1, 2, 3, 4 *or more drops of a 1 per cent.* solution of trypsin, in turn, and 1 drop of each of the dilutions is placed on one of the Petri dishes, and near it is deposited a control drop of the pure trypsin solution. The dishes are then incubated for an hour at 50 C. The drop of trypsin digests out the milk casein in the agar mixture and

the antitryptic index is the number of drops of the solution mixed with the serum which are required to overcome the antitryptic power of the serum. Four drops is the highest normal range, and any index over this is strong evidence of the existence of malignant disease. The details of fifty-three cases are given in full and the findings tabulated—the whole forming, they think, an important brief in favor of the differential importance of this simple test.

33 *"Blood Diseases." (Les syndromes hématiques associés.) M. Labbé and Laignel-Lavastine.

33. **Blood Diseases.**—Labbé and Lavastine report two cases of chronic purpura and hemophilia in a girl of 16 and a woman of 34, the latter presenting also the signs of pernicious anemia. They comment on the fact that the so-called blood diseases are rather syndromes due to histochemical changes in the blood, resulting from a variety of causes. The clinical evolution of the cases and the action of the treatment instituted show that the three syndromes were not interdependent but merely casually associated. Under serotherapy the tendency to hemophilia was arrested in both patients; the first patient recovered, but the pernicious anemia in the other continued its fatal course unmodified.

36 *Case of Rapid Actinomycosis. E. Schwartz.

36. **Actinomycosis.**—Schwartz' patient was a farmer who felt a sting on his cheek while sitting in the grass; a hard and painful tumor developed at the spot. It was excised the sixth week and proved to be an actinomycotic process. The true nature of the process had never occurred to any one or potassium iodid would have been given and operation not attempted, as it is liable to induce metastatic embolism. Letulle has recently encountered a case of circumscribed actinomycotic pleurisy in which the focus was excised and a few weeks later the patient succumbed to a metastatic abscess in the brain.

41 *Insufficiently-Fed Infants. (Etude clinique de l'hypoalimentation chez les *nourrissons*.) P. Merklen.

37. **Developmental Defects Connected with Suprarenal Lesions.**—Apert reviews the necropsy findings in thirty-five cases of disease of the suprarenal cortex on record and describes the symptoms that had been observed in the individuals during life. They form a special syndrome different, he declares, from that of Addison's disease, but almost equally distinct. In fact there are two syndromes, he says, one resulting from excessive functioning and the other from defective functioning of the suprarenal cortex. The former is characterized by excessive development of the hair and of adipose tissue and of the body in general, with disturbances in the genital functions, while defective development in these directions is the result of imperfect development of the suprarenal cortex. He applies the term "hirsutism" and "progeria" to these different types and states that the former may reveal the presence of a tumor, possibly a cancer, in the suprarenal cortex, the removal of which is urgently indicated, while in the progeria type—senile dwarfism—organotherapy is indicated, the suprarenal capsule itself being administered and not an extract of the medulla.

41. **Insufficiently Fed Infants.**—Merklen comments on the crying of the infant when it does not get enough food at a meal, its restlessness and its gradual exhaustion and dropping to sleep, the whole picture being very different from the fatigue and slumber of the well-fed healthy child. Even during its sleep the child is still restless, and it whimpers at times, while the slightest noise rouses it, when it appeals anew for the nourishment it needs without having the strength to make its appeals very insistent. There is also, he states, a marked tendency to a false constipation, not enough food being obtained to make normal stools; the walls of the intestine, suffering from lack of nourishment, grow too weak to move the feces along. Sometimes this supposed constipation is the first sign to call attention to the fact that the child is not thriving. In other cases, the stools are regular but they have the aspect of those with ordinary enteritis; even diarrhea may be observed. The stools may be fluid even when the bowels can be moved only with a suppository. These diarrheic stools alternated with periods of constipation in one of the four cases reported in detail. The possibility of insufficient nourishment should never be forgotten as, if gastro-intestinal infection is assumed and the food still further reduced, serious trouble may follow. In two of his cases the infants vomited frequently; as a rule, the vomiting in these cases follows not long after the meal. The true cause for the vomiting can be detected by noting the amount of food the child is obtaining and the improvement that follows an ampler ration. One of the four children vomited in the morning before it had had any food. Another sign of defective nourishment is the small amount of urine although, like the constipation, it is a false oliguria; it was pronounced in three of the four cases reported. The way the child nurses is also characteristic, sucking slowly and stopping often; or it sucks and no swallowing movements can be detected. Some infants give up when they realize the futility of their efforts, and lie with open eyes or in a somnolent condition, while others fret incessantly. The flabbiness of the muscles is another sign, while the wrinkled skin and pallor also attract attention; but the infant's eyes are bright and its glance is vivacious until the defective nourishment becomes actual inanition. If recognized in time and the child is properly fed, it recuperates, he says, with astonishing rapidity.

46. **Diagnostic Importance of Albumin in Sputum.**—Gantz and Hertz applied tests to determine the presence of albumin in the sputum of 125 patients, each examined two or three times. The group included only sixty with known tuberculosis. The simplicity of the albumin test and its reliability in revealing an inflammatory process in the lung or pulmonary edema commend it for general adoption, they assert, as a valuable bedside test. The albumin reaction is not obtained in bronchial catarrh and it is dubious in fibrous pulmonary tuberculosis, but it is positive in advanced and incipient tuberculous pulmonary lesions, in pneumonia and embolism and in even slight pulmonary edema. The test was made by adding 2 c.c. of acetic acid and 10 c.c. of dis-

tilled water to 10 c.c. of sputum. The mixture was then stirred briskly with a glass rod, filtered and the filtrate boiled, when the albumin was thrown down. It was sometimes necessary to add a little sodium hydroxid when the fluid was too acid.

60 *Stammering. (Zur Psychologie und Therapie des Stotterns.) O. Aronsohn.

56. **Salvarsan and the Wassermann Reaction.**—Lesser emphasizes that medication in syphilis should be guided by the reaction to the Wassermann test, as he believes that only when the test is permanently negative can the disease be regarded as inactive or cured. The aim should be, he thinks, to give the salvarsan in doses that will tone up the organs and enable them to manufacture the necessary antibodies, giving up the idea of trying to kill all the spirochetes at one stroke. This tonic action on tissues and organs is realized better with small than with large doses; the latter have a toxic action and impair functioning rather than stimulate it in the various organs. His experience has been that the best technic on these principles is to inject 0.1 gm. of salvarsan, in suspension in oil of sweet almonds, once a week, according to the technic for injection of the insoluble mercurial salts. He thus injects 0.6 gm. of salvarsan in all in about 6 c.c. of oil. A week after the sixth injection the Wassermann test is applied and if the findings are still positive he continues the injections. These small doses are convenient for outpatients, and he advocates having the salvarsan put on the market in 0.1 gm. doses already mixed with the oil.

59. **Puzzling Physiologic Apical Findings.**—Laser has encountered a number of cases in which patients had been sent to a sanatorium for lung diseases on account of supposed pathologic percussion findings at the apices, but time revealed that the apices were physiologic. He comments on the trail of broken engagements, distress and poverty liable to follow a mistaken assumption of tuberculosis, and describes the features of the percussion findings at the apex which differentiate the physiologic from those with tuberculous processes. The patients in the cases he has encountered were mostly girls, inclined to be pale and thin, complaining of lassitude and cough, and some with mucous expectoration. The area of resonance over the right apex was abnormally small; frequently the right apex dragged behind, and the breathing sound was more distinct here than in the left apex; especially over the right supraspinous fossa the expiration sounded peculiarly loud and long, but there were never any râles, bacilli in the sputum or fever. These findings persist unmodified for years and if other persons not suspected of tuberculosis are examined systematically, as Laser has done on a large scale, similar findings will frequently be discovered in the healthy. He is inclined to explain them as the result merely of an unusually wide lumen of the right bronchial tube—a physiologic occurrence. In some people both apices present the same findings, and they are liable to occur in slender men as well as in women. Blümel has recently called attention to similar findings in persons unable to breathe freely through the nose, and in looking over his records Laser has also found it noted that some of the patients in question were mouthbreathers

60. **Stammering.**—Aronsohn explains stammering as a psychologic infirmity. These individuals are generally morbidly afraid of laying themselves open to ridicule and consequently they strive to suppress emotional stress on what they are saying. Treatment should be along psychologic lines, he affirms. It is irrational to try to train the muscles to coordination when the trouble is in the mind and not in the muscles. The main point is to teach the individual to think *simply and to express himself simply and genuinely, paying no* attention to the way he speaks. Reading exercises are useful adjuvants except when the patient does not stutter when reading aloud.

Centralblatt für die Grenzgebiete der Med. und Chir., Jena

December 30, XIII, No. 23, pp. 881-928

61 *Hernia in the Linea Alba. (Hernien der Linea alba und ihre Bedeutung für die innere Medizin.) L. Müller. Commenced in No. 22.

61. **Epigastric Hernia.**—Müller summarizes in turn the principal points of sixty-eight articles that have been published bearing on hernia in the linea alba and its importance for internal medicine. The insignificance of the objective findings in comparison with the serious stomach and intestinal disturbances is a prominent feature. In one of Sebba's cases, a woman of 46 had suffered for eighteen years from gastrointestinal disturbances with repeated green vomiting; finally symptoms of ileus developed. This led to the discovery of the epigastric hernia hidden behind the unusually thick layer of adipose tissue in the abdominal wall. Richter warns that the hernia may easily escape detection unless the patient is examined standing with the trunk bent forward. In the dorsal decubitus the hernia becomes spontaneously reduced and escapes discovery. A history of work requiring much bending forward and backward, carrying heavy loads, and other factors tending to weaken the upper abdominal wall, may give the clue to the source of the trouble, as these factors are seldom encountered in the history of gastric ulcer. The increased intensity of the symptoms after physical exercise also speaks more for hernia than for ulcer; the discomfort with the latter is generally associated with food. Temporary relief from discomfort is often obtained with ulcer when the patient lies on the right side, but with hernia, relief is obtained by reclining on the back. The tenderness also is more localized and constantly at the same point. Gastric ulcer is more common in anemic girls, and hernia in robust, hard-working men. Stomach colic and localized pain in the linea alba may sometimes result from purely nervous causes, from intercostal neuritis after influenza, from gall-bladder disease, pancreatitis or appendicitis, enteroptosis, and retroflexion of the uterus. In two cases reported by Mezger the disturbances were relieved by operative treatment of the epigastric hernia but recurred later and an accompanying or causal gastric ulcer was discovered. Ury and Strauss have reported eight similar cases and suggest that the traction from the hernia led to development of the ulcer. Kelling thinks that irritation of the nerves from the presence of the hernia may lead to secondary ulceration in the stomach by reflex action. Capelle has reported that the thirty-five patients with epigastric hernia who have been given operative treatment at the Breslau surgical clinic, were all apparently cured but reexamination a year later showed that the cure had been permanent in only *nine*; the others had more or less disturbances and the hernia had recurred in six. In seven cases non-absorbable sutures and cicatricial adhesions were probably responsible for the trouble; seven other patients complained of gastric disturbances and an ulcer was probably responsible in two. A truss is of little use for epigastric hernia as it will not stay in place at this point.

73 Biogenesis and Ontogenesis. (Haeckels biogenetisches Grundgesetz und das ontogenetische Kausalgesetz von Oskar Hertwig.) F. Keibel.

62. **Epidemic Poliomyelitis.**—Baginsky remarks that the term "spinal paralysis" will have to be dropped as the disease is so variable and is liable to include meningeal, bulbar and spinal symptoms. He urges sending out a question blank to the physicians in the district to get a general oversight of the conditions prevailing in the recent Berlin epidemic. It was noted at Graz that more cases developed in the surrounding country than in the town itself.

64. **Syphilis of the Stomach.**—Siegheim summarizes what has been published on the subject of gastric ulcer, gastric tumor and pyloric stenosis developing as a syphilitic lesion and a fourth form—hyperplastic cellular infiltration leading to fibrous induration. It is only three years since Brunner was able to compile from the literature thirteen cases in which an operation had been performed on the stomach on a mistaken diagnosis, the lesion in question proving to be of syphilitic origin. Surgical treatment of tertiary syphilitic lesions in the gastro-intestinal tract, Siegheim exclaims, in future should be referred to only as a historical reminiscence. The Wassermann reaction may clear up the diagnosis, as in a case he reports from his own experience: A man of 30 acquired syphilis and was given repeated thorough courses of mercurial and iodid treatment during three or four years. Sixteen years later occasional attacks of vomiting and oppression in the gastric region after eating were accompanied by loss of weight and other symptoms, dilatation of the stomach, lack of free hydrochloric acid and presence of lactic acid with radiographic findings typical of stenosis of the pylorus. All this, in connection with the fact that the patient belonged to a "carcinoma family," pointed to gastric cancer in an advanced stage. As a last glimmer of hope the Wassermann test was applied; the findings were strongly positive, and under energetic mercurial treatment all the symptoms subsided and the patient rapidly recovered apparently complete health and has no further gastric disturbances. The peculiar severity of the syphilis in this case is evident in the serious recurrence after sixteen years in the form of a gumma in the pyloric region leading to stenosis and consequent dilatation of the stomach. Einhorn has reported a similar case except that in his patient there was never any lack of free hydrochloric acid. In Siegheim's case the motor functioning of the stomach became normal but no free hydrochloric acid could be found at the last examination although the gastric functioning was apparently normal. He adds that his case teaches the importance of direct treatment of the syphilis so long as the Wassermann reaction is markedly positive.

65. **Febrile Syphilitic Lesions in the Liver.**—In Kirchheim's two cases the tertiary lesions in the liver had involved the adjoining diaphragm with perforation in one case and propagation to the right lower lobe, empyema and chronic inflammation of this part of the lung. In the other case the participation of the diaphragm in the process entailed a syndrome simulating acute pneumonia, although there had been no initial chill and the sputum was not characteristic. In the second week pleurisy with effusion developed requiring repeated tapping. The fever persisted after subsidence of the pneumonia but repeated examinations failed to reveal the clue until in the ninth week the liver was found to be enlarging and the progressive cachexia pointed to a subphrenic abscess and staphylococci were cultivated from the pus. Hemorrhagic nephritis followed with death the fifth month after the development of the pneumonia-like syndrome. The microscope disclosed typical gumma. In both cases secondary infection of the gumma in the liver was responsible for the protracted course and final fatal termination. Specific treatment had not been given in either case as there had been nothing to suggest syphilis until, a few days before death, one patient acknowledged old syphilitic infection; specific treatment then came too late. In a third case three small gummas in the liver had involved the diaphragm but had caused no further trouble, the patient succumbing later to a brief perforation peritonitis. Klemperer has asserted that ulcerating gumma alone is sufficient to cause fever; in his cases all symptoms disappeared under specific treatment.

67. **Myeloid Chloroma.**—Paulicek and Wutscher give the particulars of a case in which a chronic myeloid leukemia in a young man blended into chloromatosis. The Roentgen-ray treatment given the patient may have been responsible for the development of the latter.

70. **Traumatic Sarcoma.**—A man aged 41 was hit in the calf by an iron rod. The open wound healed in two weeks but a swelling persisted and the point became painful so that by the end of five months he had to give up work and take a course of rest and compresses for the assumed varicose disturbances. No improvement followed and the lesion was excised. The microscope showed a round-celled sarcoma, and the thigh was amputated at once but metastasis in the spine developed in a few months. The insurance company accepted without question the direct connection between the industrial accident and the following malignant disease.

71. **To Remove Iodin Stains.**—Snoy calls attention anew to the power possessed by sodium thiosulphate to cleanse the skin and linen of the stain left by tincture of iodin. He applies a warm concentrated solution of the sodium hyposulphite (as it is more generally called), to the iodin stain. A chemical change rapidly takes place, the two chemicals blending to form sodium iodid and tetrathionate which are both very soluble and readily wash off the skin and tissues. He has never observed any injurious by-effects from the procedure on either skin or linen.

74. **Scarlet Fever Complications.**—Lüdke says in the course of his study of the subject that the temperature curve is a valuable guide to the prognosis; even the slightest rise after the disease has begun to decline indicates some complication, and reduction in the amount of urine is the most certain sign of severe nephritis. He states that one attack of scarlet fever generally confers immunity, and that the character of the prevailing epidemic determines whether the disease is to be mild or severe. Special attention must be paid to the middle ear with scarlatinal sore throat; tenderness in the mastoid region and any rise in temperature should be watched for. Even with mild scarlet fever the child should stay in bed three weeks, he declares, and not be allowed to get up until repeated examination of the twenty-four hours' urine shows the absence of albumin. The disease may occur merely as an ordinary sore throat and thus escape detection.

75. **Symptomatology of Embolism in Cerebral Vessels.**—Hippel has recently encountered two cases without the usual triad of symptoms—apoplectic seizure, loss of consciousness and hemiplegia. The first patient was a young man and hemiplegia developed insidiously, the left side becoming paralyzed for a few days and then the hemiplegia subsided and the patient felt comparatively well for two days, but then symptoms typical of meningitis developed and he died in coma. Necropsy revealed embolic obstruction of the right middle cerebral artery. Wernicke has reported a similar case in a woman of 73, death occurring from asphyxia. Hippel's

patient, after subsidence of the hemiplegia, showed no symptoms of embolism, merely the syndrome typical of meningitis. Death occurred two weeks after the first sign of trouble. Walker has reported three cases of cerebral embolism with symptoms suggesting merely acute meningitis. In Hippel's second case a boy of 8 convalescing from diphtheria suddenly developed symptoms of meningitis; there was no tendency to hemiplegia and no apoplectic seizure, but necropsy disclosed extensive embolism of the right middle cerebral and internal carotid arteries involving the finest ramifications.

87. **Hemorrhage During the First Months of Pregnancy and Its Relation to Abortion Later.**—Seitz states that hemorrhage in the first four months of pregnancy occurred in 87 of the 25,000 lying-in cases at the Munich maternity, the patients regarding it as recurring menstruation, and in an additional 273 there was atypical hemorrhage, but abortion did not follow at once in any instance. The fetus however had in some cases suffered so that only 145 of the children were carried to normal term and left the clinic in good health. Treatment of the hemorrhage has not much prospect of success in preventing serious injuries to the fetus except when the hemorrhage is due to trauma or endometritis. With trauma, the hemorrhage is the result of separation of some portion of the placenta, and treatment should aim to prevent any contractions of the uterus which might separate more of it. Strict rest in bed should be enforced. Only with bed-rest for from six to eight weeks is it possible to tide the patient past the critical period when she is subject to habitual abortions at the period in question or has been having long-continued hemorrhages. Opium should be given as indicated to prevent the uterus from contracting. Long-continued hemorrhage during the first two months seems to be inevitably fatal for the fetus, but during the third and fourth month it displays remarkable resistance. In conclusion he states that in two cases the ovum was expelled without decidua after hemorrhage during the second month, but to his surprise the pregnancy continued and a healthy child was born at term; there had evidently been a twin pregnancy and after expulsion of one fetus the other continued its growth.

89. **Restriction to Milk in Treatment of Obesity.**—Hegler records the metabolic findings in a number of persons taking the Karell cure, namely restriction to less than a quart of milk a day, the patient staying in bed, the bowels being kept loose with a laxative mineral water, with massage given daily—this treatment being kept up for from five to ten days. In one case the patient weighing 451 pounds, lost 101 pounds in the course of eighty days during which the Karell course had been repeatedly given and the patient never allowed over 700 calories a day. The general health was much improved and the patients felt stronger in every case. Practical experience seems to confirm the advantages of the Karell course, he states, although theoretically much can be said against such a starvation method of treatment.

92. **Salvarsan.**—Spiethoff has encountered a second case of collapse several hours after injection of salvarsan. His first case was mentioned in these columns Oct. 8, 1910, page 1331. In the second case the collapse occurred during the daytime, five hours after an intravenous injection of 0.45 gm. in an alkaline solution. The danger was promptly recognized and stimulants applied, soon restoring the patient, a robust young woman in the second stage of syphilis. In the other case the collapse occurred in the night after subcutaneous injection, and nothing was known of it in time. Since then Spiethoff has made the injections exclusively in the morning. The heart was not quite normal in either of these cases, but the collapse, he believes, was unmistakably the result of arsenic intoxication. His experience with salvarsan in 200 cases of syphilis confirms, he thinks, the advantages of the Iversen technic, first intravenous and then after four days a subcutaneous injection, with another intravenous injection four weeks later. Great attention must be paid to the heart both before and after the treatment and tobacco and alcohol must be avoided for a time. One young man attended a party eight days after injection of 0.6 gm., and he drank a great deal and smoked cigarettes, neither of which had ever previously affected him. But the next day acute heart weakness developed with which he had to contend for weeks. The action of the three poisonous substances together, the nicotin, alcohol and salvarsan, proved too much for his heart. Myocarditis and heart defects contra-indicate the use of salvarsan, Spiethoff insists, as also affections of the central nervous system localized in vital centers. Any local reaction to the salvarsan might prove dangerous under these conditions. In one of his cases a man had well compensated mild aortic insufficiency but no other pathologic findings could be detected in the heart. A few days after subcutaneous injection of 0.3 gm. salvarsan, signs of heart weakness became apparent, proving fatal on the eleventh day. Necropsy revealed unsuspected degeneration of the myocardium which had evidently become aggravated under the influence of the medication.

94. **Improved Technic for Test for Occult Blood.**—Wackers applies the test to the fluid to be examined diffused over the walls of a moist filtering paper funnel. It is astonishing, he says, how this magnifies the findings and does away with the uncertainty in case of highly colored urine. The advantages of the simple guaiac-turpentine test thus "enriched" are evident in case of convalescence from hemorrhagic nephritis, for example, permitting detection of even the slightest trace of blood in the urine. The test can be made with as little as 10 c.c. of urine.

98. **Research on Epinephrin and Other Glycosuria.**—Fürth and Schwarz report experimental research which has shown that injection of pancreas extract, turpentine or other irritating substance into the peritoneum injures the kidneys to such a degree that their functioning is seriously impaired and they are unable to eliminate salt and sugar as under other conditions. This simple explanation of the checking of the glycosuria which follows injection of epinephrin, by the injury of the kidneys after injection of almost any irritating substance into the peritoneum, destroys, they say, the foundations for Zuelzer's assumption of some chemical hormone inhibiting the epinephrin glycosuria when pancreas extract is injected into the peritoneum. Their findings also explain the familiar fact that in diabetes any injury of the kidneys is liable to reduce the output of sugar in the urine.

100. **Serotherapy in Epidemic Meningitis.**—Schepelmann reports an unusually severe case of epidemic cerebrospinal meningitis in a previously healthy woman of 26. No benefit seemed to be derived from the usual measures, including twice repeated lumbar puncture, but the thirteenth day of the disease a prompt turn for the better followed lumbar injection of antimeningococcus serum. The temperature dropped with sweating and recovery was soon complete. The only by-effects were recurring harmless urticaria and, the first day, there was some weakness of the heart requiring stimulants. He reviews the literature on the subject of serotherapy of meningitis, drawing the conclusion that all other measures have merely symptomatic action—the serotherapy alone is a causal remedy. The mortality of the disease has dropped since its introduction in Germany to two-thirds or a quarter of what it used to be, and the course of the disease is much milder and shorter. The earlier the injection is made, the better the results, and a single large dose is better than repeated small doses. Next to diphtheria, he declares, ranks the serotherapy of meningitis. No serious by-effects from its use have been reported.

112 *So-Called Alimentary Fever. P Heim and K. John.

102. **Pathogenesis of Digestive Disturbances in Infants.**—Bahrdt and his coworkers have devised a method for quantitative determination of the volatile fat acids. The apparatus combines a vacuum and steam distillation, and they record the findings with human and cows' milk, infants' stools and dog stomach content and stools. Their research was undertaken to determine the actual source and nature of the hypothetical toxins developing in the course of digestion which are assumed to be responsible for the so-called alimentary intoxication.

108. **Diagnostic Importance of Glycuronic Acid in Infants' Urine.**—Goldschmiedt described last year a simple, rapid and sensitive test for glycuronic acid in the urine, and Mayerhofer here reports the findings in ten infants. They confirm the importance of the test for clinical purposes as the reaction was found almost invariably negative in healthy infants but it became promptly positive with any disturbance in the child's health, especially any febrile diarrheic trouble. In advanced stages, the findings may become negative again as ability to eliminate glycuronic acid becomes exhausted. The test is made by adding to 1 drop of urine 2 drops of a 10 or 15 per cent. alcoholic solution of alpha naphthol. The mixture is then poured cautiously on top of 3 or 4 c.c. of concentrated sulphuric acid. Colored rings form at the zone of contact between the two liquids, and on the side toward the sulphuric acid an intensely green ring forms in case of the presence of glycuronic acid in the urine. To have the test absolutely certain, the nitrites must first be excluded, which is easily done with the diphenylamin reaction. A positive alpha naphthol reaction in combination with a negative diphenylamin reaction reveals the presence of glycuronic acid in the urine, and this finding parallels the digestive disturbances and disappears as conditions return to normal. The findings with this test explain the danger of giving camphor to infants suffering from inanition. Hochsinger recently reported serious symptoms of intoxication in an infant with cholera infantum and inanition who had been given small doses of camphor.

112. **Alimentary Fever.**—Heim and John suggest that what has been called alimentary fever is in reality more a stasis fever—a stagnation of heat, and they present arguments and evidence to sustain this view.

114 *Improved Technic for Operations on the Thorax. (Handgriffe am Zwerchfell und Herzen für Thoraxoperationen.) H. Teske.

114. **Improved Technic for Operations Within the Thorax.**—Teske found on laboratory animals that the dangers from opening up the thoracic cavity could be obviated by mechanical means to prevent the diaphragm from making excessive excursions. Traction on the manubrium before opening the chest has this effect, and he suggests traction on the costal arches on both sides as liable to prove effectual in man. After the chest is opened he pushes down the bulging diaphragm with the tip of his little finger, or a spatula, repeating this rhythmically, and he found that the respiration became slower and regular at once when this was done. In applying the compression to the diaphragm, he manages so as to give a little support to the heart at the same time. By this means it is possible to ward off the momentary arrest of the respiration as the thorax is opened up, which he regards as the chief factor in pneumothorax shock.

120. **Study of the Patient.**—The *Riforma* opens its twenty-seventh year with a special number containing brief articles from twenty-six leading internists. Baccelli closes his bedside lecture on a case of cancer involving presumably the

stomach and spleen, with the remark that as Cato, in ancient Rome, used to close all his speeches, on every occasion, with the words "Carthage must be blotted out," so he never lets an opportunity pass to reiterate that the study of the patient is the fundamental basis of all medical training, that the laboratory is made for the clinic, and that the clinic is the supreme authority at all times and on all occasions.

121. **Acute Sepsis in Children.**—Baginsky reports a case of general pneumococcus sepsis evidently originating in the tonsils. Pneumococci were found also in the appendix. In a second case staphylococci were responsible. He has noticed signs of primary visceral tuberculosis in twenty-four children dying from malignant scarlet fever in the last few years, and also in nineteen cases of malignant diphtheria but no signs of tuberculosis or syphilis were apparent in the majority of his cases of fulminating sepsis in children.

124. **Omentopexy for Recurring Ascites from Valvular Disease.**—Bozzolo reports a case in which the tendency to recurring ascites was completely cured by the Talma operation—omentopexy—to provide a collateral circulation. The patient was a woman of 30 who had had several attacks of acute articular rheumatism leaving a valvular defect with cardiac cirrhosis of the liver and abdominal dropsy. There were no signs otherwise of adhesive pericarditis and no traces of hepatitis were found at operation. A week later, the ascites had recurred and in the third week 6½ liters of fluid were withdrawn, and 8 liters again nearly three weeks later; after this the dropsy gradually subsided and by the end of two months there was no further trace of ascites and there has been no recurrence during the year and a half to date. Bozzolo knows of only one other case on record in which ascites from a cardiac defect was treated with omentopexy, and the result was equally successful.

125. **Prophylaxis of Malaria.**—Celli says that effectual prophylaxis of malaria requires time, organization, education, quantities of quinin and patient perseverance before it will be possible to eradicate the century-old plague of malaria in the endemic zones in Italy. The region is too vast for destruction of the mosquitoes by physical, chemical or biologic means, but with the aid of screening and quinin it would soon be possible to stamp out malaria even with persistence of the mosquitoes if it were not for the prejudice, the hatred of innovations among the authorities and the apathy and ignorance of the population, the obstacles and deficiencies of the rural public health service, the indifference of employers and the indolence of the local authorities. Preventive and curative quinin treatment is the natural base for the antimalaria campaign, he reiterates. This will cure and keep well the people in the endemic zones while the country is being drained and rendered fit for colonization—the ideal aim.

131. **Vertebral and Paravertebral Hepatic Dulness on the Left Side.**—Grocco calls attention to the extension on the left side of the area of hepatic dulness when the liver is enlarged. He has found the upper limit of the dulness extend for 7, 8, 10 or even 12 cm. beyond the median line in the back—a most instructive sign in some cases.

134. **Present Status of Specific Treatment of Tuberculosis.**—Maragliano comments on the increasing complexity of the morbid conditions as the tuberculosis progresses, other factors coming into play, secondary infection and the toxic products from disintegration of cells and bacteria, so that the primary influence of the tubercle bacilli is gradually overshadowed by the crowd of other pathogenic elements which in time dominate the situation. There is a vast difference, he reiterates, between tuberculosis and phthisis; the latter is a complex of dystrophic changes set in motion by the tubercle bacillus but having long outgrown its influence. Specific treatment of tuberculosis acts only on the primal tubercle bacilli and their toxins, and it is absurd to expect it to combat the other factors. If physicians will bear this in mind they will appreciate better the limitations of tuberculin treatment and not be disappointed when it proves impotent against the subsidiary but gradually overmastering factors.

135. **Chronic Thyroid Insufficiency.**—Marchiafava reports the case-histories of two men and a woman, between the ages of 44 and 55, who suffered for months or years from severe neuromuscular prostration, apathy and somnolency; they were incapacitated for business by dropping to sleep at any moment and snoring. The appetite and digestion remained normal but the face was swollen, although not edematous, and there was a tendency to obesity and chilliness; the skin was dry, the pulse weak and slow but regular, the gait uncertain and languid, the voice hoarse. The syndrome suggested possibly chronic uremic poisoning, but there was no headache or visual disturbance. He attributed the trouble to thyroid insufficiency and his diagnosis was confirmed by the prompt recovery under thyroid treatment. His records include two other cases of chronic hypothyroidism in which similar benefit was rapidly realized under organotherapy. In about two weeks all the patients had regained their strength and normal poise and resumed an active life. One patient had taken previously a long course of iodid as a preventive of dreaded arteriosclerosis, and this might have been responsible for the defective functioning of the thyroid; in the second case there had been a preceding attack of Malta fever which might have been the causal factor. The urine findings suggested chronic nephritis, but all these signs disappeared under thyroid treatment. The somnolency was the symptom that brought the patients to the physician, and the cure under thyroid treatment throws possibly some light on the mechanism of sleep. He warns that albumin and tube-casts in the urine must not always be ascribed to nephritis; his cases show that they may be the result of secondary changes in the kidneys from defective thyroid functioning and will subside as the latter is regulated.

136. **Serotherapy of Syphilis.**—Marinesco injected a few syphilitics with serum from other syphilitics who had been injected with salvarsan, but the results were disappointing.

138. **Acetonuria in Diabetics.**—The various types of diabetic acetonuria are here reviewed by von Noorden and the dietetic measures involved are discussed in detail.

140. **Abdominal Sign of Intestinal Metastasis of Pylorus Cancer.**—Tansini has noticed that with cancer at the pylorus the abdomen is sunken in, but that after metastasis has developed in the intestines the abdomen is no longer sunken in but has a normal aspect. In three such cases there was nothing to indicate the involvement of the intestines except the lack of this characteristic retraction of the abdominal walls which he has found constant with cancer at the pylorus. He was not positive enough in regard to the new sign to refrain from an operation on the pyloric cancer on that account alone. But in each instance the laparotomy revealed inoperable metastasis in the intestines.

141. **Phloridzin Glycosuria and Insufficiency of the Liver.**—Teissier presents evidence to show that the glycosuria which follows injection of phloridizin may be retarded or prevented by defective liver functioning even when the kidneys are intact. With diseased kidneys the liver may influence in part the reaction to the phloridzin test. The experiences with it show that the biologic phenomena are not simple but complex reactions, and that in pathology as in biology the functional synergy of the organs must be taken into account.

146 *Inherited Predisposition to Tuberculosis. N. J. Strandgaard.

147 The Air in Pneumothorax. (Undersøgelser over Pneumothorax.) F. Tobiesen.

142. **Foreign Bodies in Lungs and Esophagus.**—Schmiegelow describes nine cases in which under direct visual inspection it was possible to remove the foreign body promptly and without injury.

144. **Salvarsan.**—Rasch remarks in this discussion of his experience with salvarsan, that this drug will always stand as a milestone in the progress of medicine on account of the way in which it was introduced, instead of the manufacturing chemists casting their uncritically produced and untried remedies into physicians' hands. He adds that it is not every day that we encounter a remedy which seems to cure two diseases, relapsing fever and fowl spirillosis, while it has a powerful curative influence on two others, syphilis and frambesia, and is proving useful also in a fifth, quinin-proof malaria. He advocates giving salvarsan in syphilis in conjunction with mercury or in combination with other old antisyphilitic measures—such as antimony and potassium tartrate or chromium and gold compounds—which have recently been shown to have a destructive action on trypanosomes. A rational revival and combination of remedies has often given better results in Rasch's practice than a correspondingly large dose of a single drug, while the toxic action was much less. Ehrlich has also stated that his research on chemotherapy has confirmed the probable advantages of this method.

146. **Inherited Predisposition to Tuberculosis.**—Strandgaard has been studying conditions in eighty-nine families in which he has known of 197 cases of tuberculosis, and tabulates the details for comparison, listing the stage and extent of the pulmonary affection, the age at which it developed, the special symptoms and complications and the course. In twenty-three of the cases a parent and child were affected, in the others, brothers and sisters only. He does not draw any general conclusions.

Ugeskrift for Læger, Copenhagen

148 *Recurring Mastoiditis. S. V. W. Jantzen.
149 *Unusual Causes for Restlessness in Infants. (Et Par vigtige Affektioner hos spæde Børn.) F. Ingerslev.

148. **Recurring Mastoiditis.**—Jantzen tabulates the details of twenty-one cases of recurring mastoiditis in which a second operation was required; the total mastoid operations at Mygind's clinic during the period 1905 to date was 225. Only one of the patients with recurrence was an adult. The interval ranged from a few months to five years. He discusses the causes for recurrence and the means to avoid and treat it, reviewing considerable literature on the subject.

149. **Unusual Causes for Restlessness in Infants.**—Ingerslev discusses adhesive balanopostitis and fissure of the anus as liable to make infants fret and cry when none of the usual causes for restlessness can be discovered. He thinks that fissure of the anus is much more common than is generally recognized.

Correction.—Serodiagnosis of Syphilis.—The temperature specified in the sixteenth line of abstract 95, page 547, *Feb. 18, 1911*, should have been 55 C. instead of 65 C., as printed.

CESAREAN SECTION, WITH SPECIAL REFERENCE TO THE TIME OF OPERATION AND ITS TECHNIC *

LEWIS S. McMURTRY, M.D., LL.D.
LOUISVILLE, KY.

One familiar with the history and progress of abdominal surgery must be impressed with the similarity in the development of ovariotomy and Cesarean section. The latter operation is much older than ovariotomy, but the indications for its application are less definite and positive, and it has been universally regarded as a final and desperate effort at delivery when other measures have been tried and have failed. Like ovariotomy in its early development, Cesarean section has been fostered under the care of a few operators, who have struggled on in their efforts despite the discouragement of a heavy mortality. That the Cesarean operation is so far behind ovariotomy and hysterectomy in professional favor and in general application when indicated is due for the greater part to the fact that the surgeon competent to do the operation rarely has access to the patient until she is exhausted, often infected, by futile efforts at instrumental delivery. With patients afflicted with ovarian and uterine tumors no other operation is considered prior to ovariotomy and hysterectomy, and the operations are eminently elective, instead of being, as too often obtains with the Cesarean section, operations of emergency.

The patients requiring delivery by abdominal hysterotomy who are so fortunate as to be confined in maternity hospitals, where every modern facility and surgical skill are at command, compose only a small proportion of the great number who meet the same issues of life and death amid the disadvantages of confinement in their own homes.

The late Dr. R. P. Harris, of Philadelphia, writing in 1889, reported that there had been 175 Cesarean operations in the United States with 110 deaths. He also states that from April, 1884, to February, 1885, six Cesarean sections were done in this country and all of the mothers and children died.[1] Lusk reports on high authority that in the lying-in hospital in Vienna during the nineteenth century up to 1880, not one woman had survived Cesarean section. On equally high authority, he reported that in Paris up to 1873 there had not been one successful Cesarean section in eighty years. I beg to follow this report of Lusk showing the results of the operation prior to the antiseptic era, and the report of Harris after the antiseptic era, but prior to the perfection of aseptic methods and before the general adoption of Sänger's technic, with present-day results.

In Germany the operation has attained a high degree of perfection in the hands of Sänger, Leopold and Olshausen. The latter (Olshausen) has reported a series of sixty-five cases with a mortality of 4.6 per cent. Reynolds, of Boston, reports in 1907 thirty cases without a death. In all these cases the operation was primary; it was elective, and the patients had not been subjected to repeated examination and efforts at delivery. These results mark the standard that can be attained by early examination, hospital facilities and surgical skill.

Dr. Asa B. Davis, of the Lying-in Hospital in New York, reports (September, 1910) that in a service of 68,200 obstetrical cases at that hospital there were 256 Cesarean sections performed. The maternal mortality was 14.06 per cent.; the fetal mortality 20.08 per cent. Of these, seventy-eight operations were performed by Dr. Davis, with a maternal mortality of 16.67 per cent. Of these thirteen deaths, the report gives among causes of death the following: "prolonged labor, sepsis, suppression of urine; midwife in charge for twenty-four hours"; another "prolonged labor, sepsis before admission to hospital"; and "prolonged attempt at high forceps by private physician; general streptococcemia." Twelve of the sixty-seven women had had repeated Cesarean sections; one had undergone the operation three times and one five times. In some of these cases the operation was necessitated by multiple sarcoma of abdominal and pelvic viscera, or by carcinoma of cervix and vagina; and there were seven cases of eclampsia. A study of this report will convince one that if every reasonable advantage be utilized, if the operation be not delayed and if the patient is not infected beforehand, this operation can be done under proper hospital conditions, in uncomplicated cases, with a mortality as low as that of ovariotomy.

As with all abdominal operations, the splendid results of the present time have been made possible by the discovery and perfection of aseptic surgery. In 1876 Porro made the great contribution to the operation which has forever attached his name to the radical operation. To Cesarean section as previously performed he added hysterectomy. By this procedure both hemorrhage and sepsis were materially lessened. It gave a great impetus to the operation, and in labor complicated by uterine neoplasms will remain a standard and perfected operation. The greater number of the Cesarean operations done by me have been based on this indication, and consisted of the Porro operation with retroperitoneal treatment of the pedicle. It is an ideal operation under such conditions.

[1] American System of Obstetrics, 1889, Philadelphia, Lea Bros. & Co.

In 1882 Sänger made his epochal contribution to the technic of Cesarean section. Previous to this time, after incision of the uterus and delivery of fetus and placenta, the uterine walls were left to be approximated by the physiologic contraction of the uterus. Sänger demonstrated the importance of suturing the uterine incision with deep sutures down to, but not including, the uterine mucosa, and adding a neat suturing of the peritoneum over the entire length of the incision. As a result of Sänger's addition to the technic of the operation, and the simultaneous improvement in aseptic surgery, the operation was at once followed by unprecedented success and has attained its present high place as an operation of choice.

The operation as practiced by Sänger consisted of the median abdominal incision midway of the abdomen; turning the uterus out of the abdomen before opening it; two or three sutures were placed at the upper angle of the abdominal incision and tied after the uterus was delivered to protect the subjacent peritoneum; a sheet of rubber was then placed beneath the uterus to protect the lower peritoneum; the cervix was constricted with rubber tubing to control hemorrhage; the uterus was incised through its anterior wall vertically; fetus and placenta delivered; the rubber tube removed as soon as uterine contraction obtained; the uterine sutures were of silk and were placed as already described; before any of the sutures were tied the uterine cavity was washed out with an antiseptic solution, and the uterine cervix dilated to insure drainage. The uterus was then returned to the abdomen, and the abdominal incision closed.

As in all abdominal operations, this operative procedure as devised by its author has been simplified with experience. It was soon discovered that the elastic tube placed around the cervix produced atony of the uterus and predisposed to post-partum hemorrhage; also that it frequently encircled the child's head and interfered with delivery. The constricting tube was first replaced by manual compression of the uterine arteries by an assistant. Later even this was found to be unnecessary, as the hemorrhage can be effectually controlled by the pressure of a gauze towel packed into the uterine incision while the sutures are being placed. The uterus need not be brought out through the abdominal incision, and all exposure and handling of the abdominal viscera should be avoided. At the beginning of the operation an assistant should place his hands flat on the abdominal wall, one on each side, hold the uterus steady, and keep the abdominal wall closely in apposition with the uterus. A double tenaculum at the upper angle of the uterine incision, another fixed in the lower angle, will give the operator perfect control of the uterus while incising and suturing that organ. The utmost care should be observed to protect the peritoneum from the amniotic fluid. Davis assures us that in no instance has he found it necessary to dilate the cervix to secure drainage. No application of any kind should be made to the uterine cavity after the fetus and placenta have been delivered. The suture material best adapted for the uterine incision is chromic catgut, No. 2. The after-treatment is the same as that of other abdominal operations.

The operation should be performed with the same deliberate care and expedition as are observed in other abdominal operations. There seems to be a general impression on the part of surgeons that exceptional rapidity bordering on haste should characterize the steps of the operation. There is no valid reason for this. Davis makes the abdominal incision above the umbilicus, and the uterine incision just below the fundus of that organ. I do not believe that the site of the incision is of essential importance. The abdominal wall at the full term of pregnancy is thin and relaxes easily. As soon as the abdominal incision is made and the uterus exposed, long gauze pads wrung out of warm salt solution are placed within the abdomen to hold back the omentum and intestines and protect peritoneal surfaces while the uterus is being emptied and closed.

Unfortunately, in the majority of cases, the operator has no choice as to the time of election for the operation, the patient being usually in active and prolonged labor when he is called on to operate. When the patient is under observation in advance and choice of time for operation can be made, it is preferable to operate after labor has assuredly begun. To elect this time from the menstrual history is inaccurate and will not infrequently result in the delivery of a premature child. No dilatation of the cervix or preliminary vaginal operation, other than thorough cleansing of the vagina, should be done.

With the demonstrated results of Cesarean section, as now obtained, the scope of the operation must necessarily be widened and its application greatly extended. What is most needed at the present time (and this thought has inspired this paper), is an active interest on the part of all abdominal surgeons, and such a campaign of education as was successfully applied some years since in behalf of early operation in other conditions requiring prompt surgical intervention. It is established that the primary Cesarean operation in skilled hands has a mortality quite as low as uncomplicated ovariotomy and clean hysteromyomectomy. With repeated examinations, cervical dilatation and application of forceps, carried out with crude and desultory observance of aseptic precautions, the mortality of abdominal hysterotomy is unnecessarily increased. The cooperation of the surgeon and the general practitioner is necessary to correct this fatal error.

Fourth and Chestnut Streets.

THE MOBILIZATION OF JOINTS BY MEANS OF THE RUBBER BANDAGE

A. C. STRACHAUER, M.D.
Associate Surgeon, Minnesota University Hospital
MINNEAPOLIS

The mobilization of joints is a common field of neglect. The patient with a stiff joint following fracture is often told that time alone will bring a restoration of the normal range of motion, which is in a degree true, but the patient so dismissed feels, and is, neglected, for much time can be saved for him by proper treatment. Not this alone, but many a brilliant success in fracture treatment is greatly overshadowed in the patient's estimation by the resultant stiffness following the removal of splints. In addition to the cases in which time alone usually successfully obtains the normal range of motion, is the group of immovable joints, and cases of limited range, which, if neglected, do not improve, and which, with the exception of those of bony ankylosis, exuberant callus or displaced fragments following fracture—cases of mechanical obstruction to be relieved alone by operation—brilliantly respond to proper treatment in various degrees.

The causes of the stiff joint following fracture, exclusive of the results of direct injury of the joint, are: edema, atrophy, shortening and loss of elasticity of muscles and the periarticular tissues; cicatricial contraction and fibrous changes, more common in suppurating open fractures, and traumatic arthritis. This stiffness of joints, as is well known, obtains not only in the structures directly involved but in the related joints of the extremity, due to a coincident sprain or to enforced quiet, as a part of the dressing; i. e., stiff knee after fracture of thigh; stiff elbow, wrist and fingers after fracture of arm.

TREATMENT

Massage, hot and cold baths, high dry heat, active motion, *less passive motion,* and the method of mobilization by means of the rubber bandage to be now described, and which is not intended to replace or minimize the importance of the first mentioned measures, constitute the treatment.

Gradual strong flexion and extension is obtained by the application of a rubber bandage of the ordinary 2½ inch variety, or of double weight for most of the dressings. The manner of the application is made in accordance with the indications and requirements of each case, and is so made that the contraction of the bandage takes place in the line of the desired increase of motion; that is, in the line of normal movement.

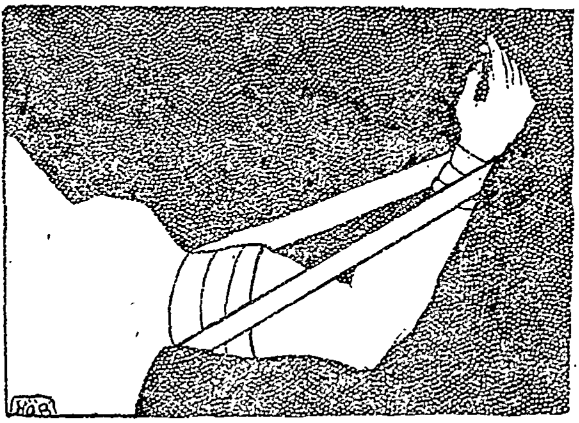

Fig. 1.—A method of securing flexion of the elbow-joint by means of a rubber bandage.

The elastic contraction of the rubber bandage by its gradual, even, confidence-gaining quality, overcomes, first, the voluntary and spasmodic contraction of the guarding, protecting muscles and tires them out. Complete relaxation is so obtained, at which stage the contraction of the rubber bandage is exerted on the shortened, contracted structures and mechanically stretches them. By this means, at one sitting, a range of motion far greater than can be obtained by passive movement is realized, which is not followed by so great an irritative reaction and which is not so painful as effective passive movement. The patient's confidence in making greater active movements is also greatly increased by the demonstration of the degree obtainable with the rubber bandage, and his cooperation from now on is obtained.

A small amount of pain and discomfort is permissible during the treatment, the length of which is controlled by the patient's fortitude and disposition, the rule to be strictly adhered to being that the joint should not be tender on the following day. The first several applications are made every second day, after which they should be made daily.

Joints of false or fibrous ankylosis, in which there is no danger of making active a quiescent infection, should be broken up under anesthesia, the reformation of such ankylosis prevented, and the mobility increased by beginning on the second day following the forcible procedure, the application of the rubber bandage method.

TECHNIC IN SPECIFIC CASES

The Elbow-Joint.—For flexion: Secure the initial extremity of the rubber bandage without stretching by several circular turns around the forearm, just above the wrist; carry the stretched bandage to the upper end of the arm, making one unstretched circular turn around the limb, and then return with stretched bandage to the starting place above the wrist, where a single circular unstretched turn is made. Repeat the application between the wrist and arm several times with the bandage on the stretch, omitting the circular turns (Fig. 1). In certain cases it is of advantage to modify this dressing and those portions of the following in which the rubber bandage is secured by completely encircling the limb, by fastening by a gauze or muslin bandage at such places a large wooden curtain ring of the ordinary variety, the stretched rubber bandage being then carried through these rings instead of surrounding the limb, so insuring security and avoiding any possible constriction of the circulation (Fig. 2).

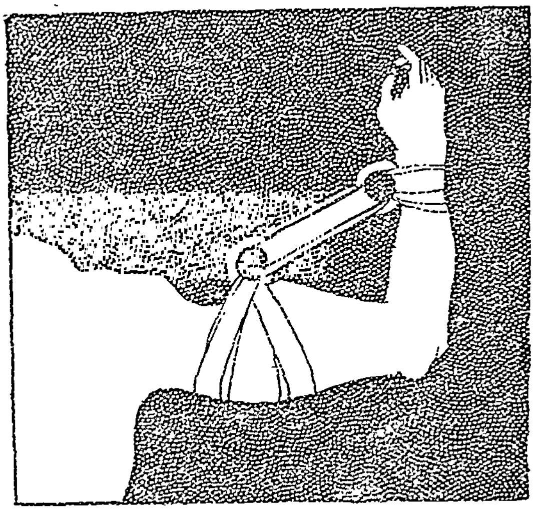

Fig. 2.—Another method of securing flexion of the elbow-joint; curtain rings are secured to the arm and wrist, through which the rubber bandage is drawn.

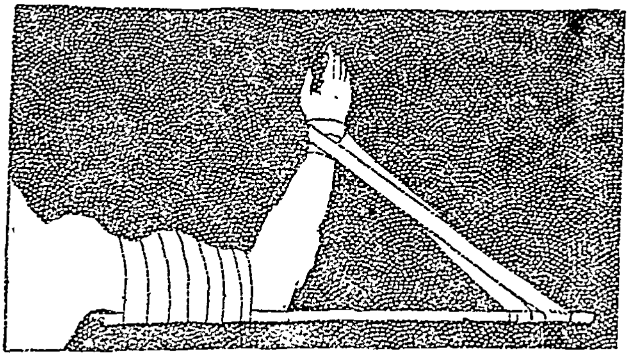

Fig. 3.—Method of securing extension of the elbow-joint. A straight splint is secured to the arm by means of a roller bandage and extension is made from the distal end of this by means of the rubber bandage encircling the wrist.

For extension: Fasten securely to the arm, by an ordinary gauze bandage, a firm, straight posterior splint, somewhat longer than the length of the complete upper extremity. Secure the initial extremity of the rubber bandage by several unstretched circular turns around the forearm just above the wrist; carry the stretched bandage to and around the free extremity of the posterior splint, and return with stretched bandage to the starting-place, repeating the application between forearm and splint a half a dozen times (Fig. 3).

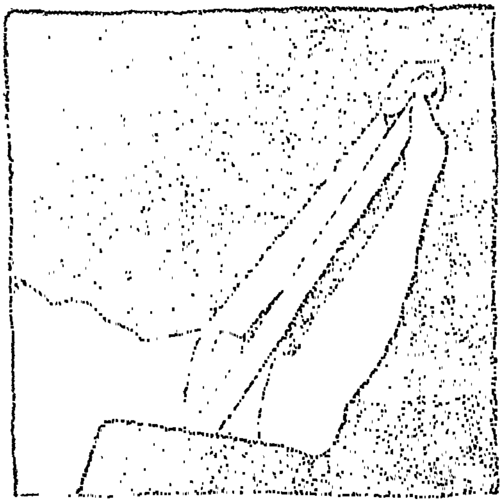

Fig. 4.—Method of securing extension of the wrist. The rubber bandage encircles the arm above the elbow and the hand around the palm.

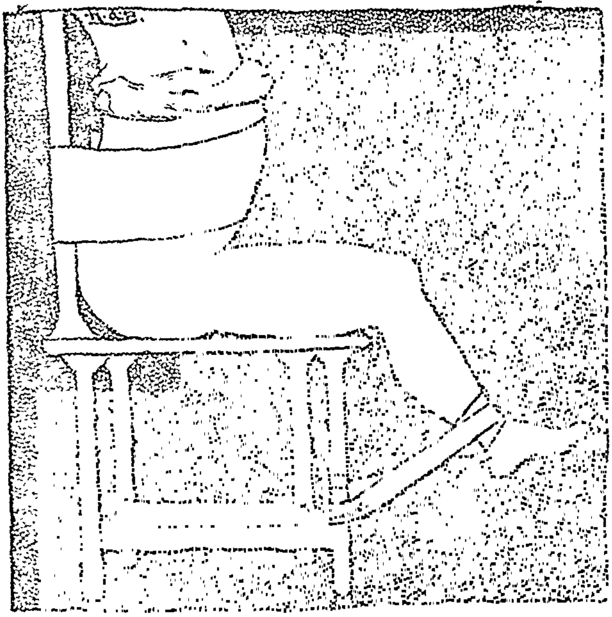

Fig. 5.—Method of applying the rubber bandage to secure flexion of the knee-joint. The patient sits on a chair and the bandage encircles the ankle and the leg of the chair.
